As college lads some, perhaps most, of us were taught that Right is founded not in the nature or will of God, nor yet in the nature of man, but in the nature of things. Is there not room to believe that evil in expertism lies more in the nature of things and our imperfect legal methods of eliciting truth, than in the bias and depravity of expert man? It certainly is in the very nature of things that expert testimony, like all other testimony, whether to opinion or to so-called facts, must vary with the witnesses. Why, then, this apparent assumption that experts, even in the inexact sciences, should agree in their testimony, and that their disagreement necessarily affords presumption, if not of dishonesty, at least of bias? Because the expert avowedly testifies to "opinion" only, and is therefore not punishable for perjury, even in case of wilful falsehood, is it fair to assume that he deliberately lies more frequently than the ordinary witness? How often is that ordinary witness punished for perjury, or restrained by fear of its penalties? The address of the president of our State Bar Association, two years ago, was as harrowing a picture of the perjury of ordinary witnesses as has ever been presented when experts have furnished the artist's material. I am optimistic enough to believe that an expert is as honest as are other witnesses; pessimistic enough to think that perjury is too frequent with all classes of those who testify in court; and charitable enough to fancy that much of what many suppose to be wilful falsehood is really only the result of inaccuracy in observation, inference, memory, and understanding, supplemented, far more than is commonly imagined, by clever suggestion or by ineptness on the part of examining counsel. Ordinary witnesses, even the honest, constantly differ in their testimony as to those every-day occurrences, supposed to be apprehended immediately by the senses, and called "simple facts"; the reason being, as we all more or less distinctly perceive, that every witness is, in the last analysis, only giving an opinion.

Some men are so constituted as to accept every apprehension of sense and result of mental processes as positive facts. What they see, or think they see, they know absolutely. Others are so convinced of the relativity of all knowledge that, to them, nothing is certain; they accept mathematical axioms with mental reservations. As describing this, the nonsense aimed at John Stuart Mill almost becomes sense:

> "There was a philosopher, Mill,
> When you said 'Twice two 's four,' he said, 'Still,
> Perhaps, up in heaven,
> It makes six or seven,'
> This abnormal philosopher, Mill."

Medical jurisprudence is—contrary to what seems to be a general opinion—the science, not of applying legal principles to elucidating medical questions, but of applying medical knowledge to the solutions of legal problems; and in practice the law must derive this aid from medicine through expert testimony. It would never do for the court and jury to retire with a medical encyclopædia and "cram up."

An expert is only a person specially experienced, skilled, or learned in some art or science; or, as some would have it, in any department of knowledge or skill, wherein the formation of a sound opinion necessitates a previous course of study and experience beyond the lines followed by the average man. This expert is called upon in litigation to enlighten the court and jury by giving an opinion upon a state of "facts," either within his knowledge, or more often narrated to him for the purpose of eliciting his opinion and serving as its basis. Even an ordinary witness, if he cannot otherwise sufficiently convey his meaning to the jury, is allowed—where his testimony necessarily presents a conclusion—to give opinion evidence, providing that he recites those facts personally observed by him, which serve as the data of his opinion. The expert differs from him in this—that the former may give his opinion not only upon facts that he has observed personally, but—and to this end he is most frequently called—upon facts testified to in the case by others. Thus, both a medical man and a layman may testify upon the issue of A's sanity; but while the former may base his opinion upon facts testified to by other witnesses, the latter must narrate those personal observations of his own which have led to his conclusions; and there is judicial opinion that the testimony of neighbors to A's sanity, given under this rule, is more satisfactory than the opinion of a physician based upon a hypothetical question. But I think that if the judicial mind rendering that opinion had been analyzed, there would have been found in it an unrecognized—subliminal, if you please—impression, that the neighbor's opinion, ostensibly based upon his recital in evidence of certain erratic actions of A, rested actually upon very many observations not before the court or jury.

One class of experts in the law has a great advantage over all others. Their opinions are authority; for a time at least. I refer not to attorneys, who are rarely called as expert witnesses, save upon the point of a fellow-attorney's fees—when agreement is likely—but to that great body of experts who rarely if ever go upon the witness stand, yet are always under a continuing oath, and in every case, upon the facts before them, render their opinions as to the law—the judges. When they give an opinion, whether it be right or wrong in our opinion, it is of binding force until set aside; and that is more than can be said of yours of the faculty, or ours of the bar. I have sometimes wondered whether those judges who have been

most denunciatory of the differing conclusions at which reputable medical experts have arrived at upon the facts in evidence have reflected that they, too, belong to a body of experts in the law, whose members often differ, very honestly and ably, in drawing conclusions, even from agreed facts. You laymen would think, for instance, that it is much easier to define the word malice, to say whether a corporation is liable for its servants' malicious acts, whether certain words are defamatory within the ordinary understanding of reasonable men, and whether a criminal statute is retroactive in effect and, therefore, *ex post facto*, than it is to tell whether certain physical symptoms indicate typhoid fever or appendicitis, whether morphine poisoning can be absolutely diagnosticated from symptoms alone, or what, with reasonable certainty, is the prognosis of a morbid condition; say, traumatic hysteria. Let us see. Since memory runs not to the contrary, English judges have cudgelled their brains over the legal definition of malice; and yet, only recently, in the great case of Allen *vs.* Flood (1898, App. Cas. 1) involving that definition, two judges and six law lords reversed the judgment of ten judges and three law lords; in other words, eight judges reversed the opinion of thirteen, not because the former were necessarily wiser, but because they sat higher in the forum. In another recent English case, Neville *vs.* Fine Arts and General Insurance Company (1895, 2 Q. B., 156; 1897, App. Cas., 6) the judges, avoiding with much skill the vexed question of corporate liability for the malicious acts of servants, passed upon the point whether certain words would be ordinarily understood, by reasonable men, as defamatory. Pollock, B., Lord Esher, M.R., Lopes and Rigby, L.JJ., decided that reasonable men would so understand them. But upon appeal, Lords Halsbury, L.C., MacNaghten, Shaw, and Davey were of opinion that the words were not so understandable—in short, that Pollock, Esher, Lopes, and Rigby did not possess the understanding of reasonable men. Coming home now, across the water, we find the recent medical case of People *vs.* Hawker (14 App. Div., 188; 152 N. Y., 234; 170 U. S., 189), wherein the facts were agreed upon, and the only question involved was one of law, whether a statute forbidding one convicted of felony to practise medicine could apply to a licensed physician, so convicted prior to its enactment; in other words, whether the statute was *ex post facto*. The trial judge decided negatively. The appellate division of this department, by a vote of three to two, reversed him; the court of appeals in turn reversed the appellate division, two of its judges dissenting; and finally, the supreme court of the United States, after two arguments, affirmed the court of appeals, three of its members dissenting. Surely no one would presume, because of these differences of opinion, to doubt for a moment the ability, the learning, the absolute honesty of these various experts of the law; and it is equally manifest that the frequent differences of opinion among medical experts—the only class we are now considering—should not of themselves alone justify the criticisms so freely made. We must seek further, therefore, the explanation of our paradox.

As has been said already, judges, although experts in the law, do not render their expert opinions from the witness stand or under cross-examination; nor are those opinions, like those of other experts, avowedly to be passed upon, and they may be disregarded by the jury except when in cases of criminal libel jurors are expressly made judges of the law and the fact. In civil cases judicial opinions not only theoretically but, as a general rule, practically control the jurors in matters of law. In criminal cases, however, jurors, although directed save in actions for libel to follow the law as laid down by the court, constantly disregard judicial instructions as well as expert testimony; and while in so doing they violate a moral and legal duty, they exercise, nevertheless, a power undoubtedly possessed by them in practice under their right to bring in a general verdict of "not guilty," no matter how absurd it may be; and rarely if ever do they incur for such misconduct a greater penalty than a contemptuous rebuke and discharge from further service. Yet, although it thus appears that the jury may disregard upon occasion even the most authoritative expert opinion, nevertheless—let laymen jeer as they will at the glorious uncertainty of the law—the opinions of the judges who sit high on their thrones of awful state are hedged about, and properly and justly hedged about, with that reverence which attaches to authority. But how is it with the scientific experts? Divested of all pomp and panoply, they utter their opinions from the same stand with other witnesses, the obvious truth-tellers and the unmistakable liars, and they utter them, too, under the same procedure that is adopted to elicit what we fondly call the facts of the case.

To elicit in litigated cases the truth from minds as far as possible apart in qualities, powers, and processes, we have certain arbitrary rules of evidence. They are not careful, scientific formulations, beaten out by the brain laboriously and systematically; but they have been largely struck off by rough common sense as occasion arose, at nisi prius, and preserved for us in the museum of precedents. They have answered—they still answer—their purpose of getting at the truth approximately, minimizing lying, and putting an end, at some time or other, to litigation. But they are not to be venerated as the best guides to absolute truth. Only within comparatively late times has effort been made to systematize them. They are still to be sought among the bewildering and contradictory cases wherein substantive law is confusingly blended with the law of procedure. Our reverence for them, like our veneration of the boasted Saxon institution of jury trial, is based somewhat upon misapprehension. The jury came to us, apparently, not, as we have fondly supposed, from our Saxon but from our Norman ancestors, whose descendants in France of to-day disregard in legal procedure pretty much everything that we have come to hold sacred. So, too, our evidential rules, while serving to get at truth in a rough, everyday fashion, in accordance with our traditions and the spirit of free government, are by no means, as some fancy, the best rules for the attainment of scientific truth. If, for instance, Darwin had excluded hearsay evidence, the origin of species would never have been written; and even in ordinary affairs, there is not a day, scarcely an hour, when men, lawyers, and laymen do not, where honor, life, and property are involved, act with assurance and safety upon testimony inadmissible in courts of justice.

Undoubtedly, our legal procedure is intended and supposed to elicit the whole truth relevant to the issues of a trial. We hope and are fain to believe that this is its usual result. But let us consider for a moment its nature. Litigation means contest between two sides. The law's theory is, that each side shall have a fair field, and no favor for the presentation of so much truth as makes for its contention. Each litigant calls witnesses who swear that their evidence shall be the truth, the whole truth, and nothing but the truth; but that means that they will answer truly and reverently, not that they will volunteer speeches as the witnesses did, to the amusement and amazement of our part of the world, in the great case of recent date. The legal theory is that, between examination and cross-examination, the witness's visible supply of truth will soon be exhausted and his reserve tapped. Each side has and generally must have a theory of the case, to be supported as to matters of common obser-

vation, so-called "facts," by the testimony of ordinary witnesses to what they have apprehended, or think they have apprehended, immediately by the senses; only they are not allowed openly to confess that they only think they have apprehended. They are told to tell "facts," as though they knew any facts except with the oath of the conscious or unconscious cerebration of their thinking apparatus.

As a rule, this part of the testimony is disposed of with comparative ease, leaving upon the jury's mind rather distinct impressions. As to matters of special knowledge each side supports its theory of the case by the opinions of experts, and the examinations of these gentlemen are at times drawn out interminably and often with the result of befogging and boring jurors to the detriment of the examiner. Let us illustrate: We have an accident case, so-called. The issues are: Who was at fault? If the defendant, then what are the extent of the plaintiff's injuries, and the consequent reparation due to him? So far as the circumstances of the occurrence are concerned there are conflicting stories, and each attorney adopts, honestly we will hope, that theory of the case which best harmonizes them in his client's favor. He will not, knowingly, call false witnesses. He will not lure honest witnesses out of the jurisdiction. He will not consciously misstate the law. But probably, as a famous advocate and diplomat once said, "it will not be his chief effort to elicit all of the truth that tells against his client." When it comes to the medical theories of the case, the diagnosis and prognosis, the attorneys must necessarily resort for them to medical men, who, if honest, will make as thorough and fair an examination as possible, and advise the attorneys what, in their opinions, is the plaintiff's condition, whether it is attributable to the accident, and what can be said with reasonable certainty of his future history. Such information is absolutely necessary to attain the ends of justice, and therefore physicians were among the earliest experts called for the enlightenment of the court. They will always be necessary. The question now agitated is whether we shall go back to what it seems was the ancient method of allowing the court to select experts of quasi-judicial character to inform it, whether we shall adhere to present methods by which opposing counsel, having chosen their witnesses, beat the truth out of them—or, sometimes, keep it in them—by pitting them against one another under examination and cross-examination; or whether we shall make a blending of these methods. It is not within my province to-night to examine these proposals or the objections to them. That has been done already better than I could do it. My only function is to point out what defects are in the very nature of expert testimony, and what are in our methods of adducing testimony.

It is objected that under our present system experts become partisans—"hired advocates," as we lawyers are called by those deeply conscious of their own unselfish virtue—medical counsel, who, unlike legal counsel who rarely if ever testify, go upon the witness stand to plead a cause, not to tell the truth. I have already intimated my belief that this opinion is exaggerated. Experts are unprincipled sometimes, of course; but I do not believe they are so—I should bitterly regret to think they were so—as a rule, and prefer to think the criticism superficial. In a celebrated trial for murder, medical and chemical experts of the highest personal and professional reputation were subjected by some to very harsh condemnation because of their differences in opinion as to the possibility of diagnosticating morphine poisoning from symptoms alone. But it seems to me that, to one reading the record of that trial carefully, these inferences became largely reconcilable, leaving no reason to impugn good faith. It may well be questioned whether a different result would have followed if the scientific witnesses had been official experts or had passed State examinations and registered, as it has been suggested all experts should be required to do before being recognized as such. Certainly, if the experts in that case differed corruptly and not honestly, if they espoused under oath theories they did not believe, we might well despair of the honesty not of physicians only but of mankind. It would be fortunate, no doubt, if as a general rule in every case each party could have medical counsel to frame the medical theories of the case and suggest physicians or surgeons imbued with those theories who might be called to testify in support thereof. We may concede that it is a theoretical defect in procedure that compels us to call an adviser as a witness; but before essaying to remedy the defect by a rule forbidding such practice, it is to be borne in mind that occasions may often arise when the witness may necessarily have to be also the instructor of the side calling him. If, for example, in the day of Jenner a case had turned upon his much-opposed theory, would he not have had to be called both to advise and to testify? Many like illustrations will suggest themselves, and it is not to be forgotten that every advocate wants to know what his witnesses will testify to before calling them, that he is entitled to call any one who can testify honestly to a theory that sustains his client's cause, and that, if need be, he has a right to learn that theory from the person who may be the only available witness to maintain it.

It is, perhaps, in qualifying the witness that our procedure is most defective; and beyond doubt much of the disrepute into which medical expert testimony has fallen is due to the fact that our courts, through laxity or inability to test special fitness, too often allow incompetent men to testify as experts. There is at present no certain standard in this regard for judicial guidance. The latest utterance of our own court of appeals upon the subject is in the case of People *vs.* Rice (159 N. Y., 400), which holds that a license to practise medicine, while *prima facie* truth of expert competency, is neither conclusive nor essential. Upon that point the general rule seems to be that any physician may be admitted to give testimony in any department of medicine; but there are jurisdictions in which it does not obtain; and I do not think that medical men themselves are disposed to regard it with favor. One of your own profession (Dr. Pearce Bailey, in MEDICAL RECORD, March 4, 1899), in writing lately upon the medico-legal relations of traumatic hysteria, declares the result of his observation and experience to be that "a large number of medical witnesses who qualify as experts in litigated causes of traumatic hysteria have no rational conception of what hysteria is, and are totally unable to give an expert opinion in regard to it." From this premise he infers that no matter how honest or distinguished such practitioners may be, their testimony is "fatal to all attempts to arrive at the truth of the issue." Possibly a wise system of examination might secure a permanent class of highly qualified experts, but it is more likely that the system's value would lie not so much in securing competent men as in excluding ignorant pretenders to medical knowledge. As it is now, counsel in great cases seek the best learning they can find; yet a layman's clever cross-examination may discredit a witness reputed to possess and, in fact, possessing knowledge far greater than that of the class who would be most likely to aspire to positions upon a State board or care to be listed in a class of professional witnesses. In the murder case already referred to, a gentleman of national repute, an authority among medical writers, testified that in his opinion opium or morphine poisoning could not be positively diagnosticated from symptoms alone. He said that he based his opinion

on his reading and very largely on his own experience. His cross-examination was very brief. It consisted substantially in asking what was his experience, and the number of cases to which he had been personally called in recent years. He admitted with perfect candor that within twenty years he had seen but three cases of opium poisoning, and one case of morphine poisoning. Having admitted that what convinced him of the cause of death was, in one case, the autopsy, he was then asked whether he had ever diagnosed such a case without an autopsy, and also asked whether he thought himself competent with this limited experience to testify against physicians who in the same time had seen seventy cases and were constantly seeing them. No one well informed in the premises doubted the learning, candor, and ability of the witness, nor could exception be taken to the cross-examination which deprived his testimony of any force. No law can be framed constitutionally, that would preclude such a cross-examination. And it is food for thought whether it would be desirable to have members of a State board frequently put through such a course of questioning.

Another defect in procedure is said by experts to be that we lawyers will not let them tell the truth even when they want to. One distinguished gentleman who has testified very often as a chemical expert, in a letter written to Mr. Tracey Becker and by him incorporated into an interesting paper before the Central Medical Club at Buffalo last year, thus complained: "In all my employment I have found the task of keeping the counsel who was to examine me in chief within the bound of my convictions much more troublesome and difficult than the most searching cross-examination." This is a sad picture of chemical counsel struggling with legal counsel on the same side for a chance to tell the truth; and obviously there is no remedy for such a state of things except to let this expert address the jury, as M. Bertillon lately did in France, or submit written opinions. But with all due allowance for undue zeal or the inability of many examiners in chief to develop the case, we may still consider this to be about as sweeping as the assertion of Mr. Dale, of the Philadelphia bar, under whose leadership the bill drafted by a committee of the Pennsylvania State Bar Association to regulate expert testimony was referred back to the committee without approval at that association's meeting last summer. He said: "We all know that men whose minds are devoted to the subject of insanity acquire a peculiar bent, so that the large majority of the eminent men who have studied insanity, and are called upon the witness stand to express an opinion as to the mental status of any particular person, will invariably, and with entire honesty, state that those men are insane"; and, in the spirit of prophecy, he said that, if the bill should become a law, successful prosecutions for murder would in that commonwealth be at an end.

Still another defect, as some take it, in our method of eliciting expert knowledge is the hypothetical question; and the bill of the Pennsylvania Bar Association just referred to proposed to do away with it entirely. But, on the other hand, our courts have expressed themselves often as considering the hypothetical question the best if not the only means of eliciting opinion. Time does not suffice to discuss this topic in detail.

To the minds of many, it is in the contingent fee, especially in connection with lack of qualifications, that the source of most of the corrupt practices on the part of the lawyers and experts is to be found. As you know, acceptance of a contingent fee was once considered disreputable among attorneys. We all remember how slyly Sam Weller slipped into his testimony the remark that it was very honorable and generous in Messrs. Dodson and Fogg to take the Widow Bardell's case "on spec." But the widow won from the jury nevertheless, and contingent fees were taken notwithstanding their theoretical impropriety, based upon the idea that all persons, attorneys not excepted, will lie and cheat in their own interest if given a chance, a reason for which persons in interest were formerly forbidden to testify. Now our code expressly allows contingent fees to be taken by attorneys, whether wisely or not we will not consider; that, too, being a point upon which expert opinions differ. Parties now may testify in their own interest, even prisoners charged with crime. With all these classes of witnesses, the jury is directed to consider their interests in weighing the evidence; and it certainly seems proper to show to the jurors what interest the expert may have, that they may consider it—although in this regard courts and counsel are generally considerate of the witness; it will then be for the jury to weigh expeft testimony and decide how far the balance is affected by motive. It is our belief in the freedom of the judges from bias that, probably more than any other reason, differentiates in the public mind their opinions from those of scientific experts. Yet while we thus believe in the honesty and fairness of our judges, conspicuous examples are not lacking where their opinions have been assailed by large numbers of persons who, whether right or wrong, have firmly believed their determinations to have been influenced by extra-legal reasons operating consciously or unconsciously upon the judicial mind. Thus the *London Law Times* of December 18, 1897, suggested that "it is curious that politics took sides perhaps involuntarily" in deciding the case of Allen *vs.* Flood above referred to. The same periodical in the following week cited from a speech of Lord Brougham to show that in his very recent day the decisions of English judges could be predicted from their political leanings. In our own country there are those who think—wrongly, let us hope—that the decisions of the Electoral Commission and of the Surratt and Income Tax cases, while not due to gross pecuniary motives, were due to influences outside of the record. But in mentioning these cases I cannot make it too clear that personally I am far from sharing such beliefs, nor do I believe that even a small percentage of members of the bar entertain doubts of the judicial fairness. The cases are cited only to show that even our highest and purest sources of opinion will be suspected and assailed by those prone to think evil whenever there is plausible ground for suspicion, and therefore it is not to be wondered at if men even of reputation and character fall under condemnation when their testimony is given, or supposed to be given, in the understanding that their reward will be large or nothing, according as the theory for which they are called shall prevail or fail.

The last objection to our present system of eliciting expert opinion is that it begets intolerable prolixity, due often to counsel's lack of preparation, sometimes to his exuberance of knowledge. In the court's power to limit examination and cross-examination within reasonable bounds, some see a remedy for this evil; but here again to discuss the remedy would be to transcend my own limits.

The subject, as you know, is not new and abounds in difficulties. We are not to determine the questions it suggests to-night; but we will achieve something toward its determination, perhaps, if our discussion sets lucid minds to work upon the problem. How vexed that problem is a few recent examples will show. In 1898, a bill was introduced into the New York legislature framed by a conference of physicians and lawyers appointed by various learned bodies of this State. When it was read in the State Bar Association by the delegate of that body, it met with some approval, but with so much more dissent that upon its reference

back to committee with instructions to report, that latter body considered it not worth while to take further action in the premises. In the following year, in the last session, another bill, approved, I think, by this Academy, failed to become law.

The bill of the Pennsylvania Association already referred to was carefully drawn, following in the main the lines of Judge Endlich's address to that body, which you may find in volume xxxii. of the *American Law Review* at page 51. It, too, was referred back to committee, after an interesting discussion which will appear in the report, which I cannot even summarize in my brief time, although advance sheets have been sent to me with great courtesy by the association's secretary.

In Illinois, a report was made last summer to the State Bar Association by a minority of a committee appointed to consider the subject, the majority not having convened. That report is terse. Avowing inability to formulate legislative remedy for the evil that we all admit, it expressed an opinion that such remedy can be found in the exercise by the courts of their existing prerogatives, and in the cultivation of high professional standards by bar and faculty.

What has struck me more than anything else, in reading the various essays and reports upon this topic, is the small consideration given to definitions, which are the starting-points of accurate inquiry.

At the risk of uttering trite knowledge, let me remind you in closing how vague our ideas are apt to become upon matters whereon we feel assured. The line between opinion evidence and evidence as to fact is as vague as that between sanity and insanity. Statements of "opinion and belief" differ from "statements of fact" only in that the first two, which are usually convertible, indicate the witness's consciously reasoned judgments short of certainty or convictions; whereas the latter are expressions of his certain judgments based upon perception and unconscious reasoning or inference. It has been often pointed out that we use the word "belief" to express our flimsiest guesses, as well as our deepest convictions. We say with reverence that we believe in God, and with carelessness that we believe it will rain before the week is out. What we assert absolutely as the perception of our senses is often only inference. A man was lately sentenced to death upon an honest witness's testimony that he saw the prisoner chase, stab, and fall upon the deceased. Upon a new trial, it was shown that, while the prisoner did pursue deceased, it was the latter who in his flight drew the knife and, essaying to turn upon his pursuer, fell upon it and died, the prisoner falling upon him. What the first witness saw was the pursuit and the flash of the knife. The stabbing was his inference due to the perspective from his point of view, but it was accepted as a fact. Pardon me if I recall the commonest deceit of our untrustworthy senses. Squibsters and their readers have laughed inextinguishably over Deacon Jasper's preaching that the "sun do move," but Jasper and his congregation see it moving every day, and know that if the earth turned over they would fall off. For sixty-seven hundred of our planet's seven thousand historic years, every one was of Jasper's opinion. Ptolemy apprehended that the earth's diurnal rotation would account for many unexplained phenomena. But there was the lack of variation in the perspective of fixed stars and other stumbling-blocks; and so his geocentric theory was accepted until Copernicus and Kepler came along the other day with their larger explanations, and now the semi-educated laugh loudest at Jasper. But how many here to-night would enter the list with Ptolemy in support of the heliocentric theory as against the geocentric? Some, I have no doubt. Mr. Lewis, I feel sure; but not I, for one, with my remembrance from college days that Benjamin Peirce, the giant of our mathematicians, once said that Ptolemy's theory would reconcile all phenomena as well as the Copernican only by such a complexity of reason as few minds could grasp; wherefore science adopts, as always, the simple hypothesis, trusting that in the great autopsy of the universe the latter-day experts will be proved to have been right. Witnesses, whether experts or laymen, are constantly hectored and called upon to testify to "facts" by attorneys who have little realization of what a "fact" is, and no habit of questioning the testimony of their senses. Apropos of this you will appreciate a recent utterance put forth in Tremont Temple, Boston, on the fifth day of this month, by a gentleman of whom I would speak with great respect, reputed to have been a friend of Mr. Lincoln, a district attorney under Mr. Cleveland, a former judge, and so sincere that he declined renomination to the bench in order to do a work that you and I scarcely consider worthy of such a disciple. Here it is: "My only art will be the simplicity and courage of conviction, my only argument a statement of facts; and, after all, how resistless is the potency of a fact? The sole purpose of inquiry in every court of justice in Christendom is, and ever has been, to invoke facts; the world is weary of theories, it longs for facts; it is surfeited with dogmas, arguments, and platitudes, and cries out for facts." Now, what do you suppose the "facts," the indisputable facts were to which this worthy gentleman, judge, and lawyer—presumably habituated to weighing evidence—fancied he was testifying? Why, that God Almighty had failed to make His gospel clear until 1866, and had then revealed it to that very shrewd lady of Massachusetts, Mrs. Mary Baker Glover Patterson Eddy, whose new evangel of spirit and health this estimable gentleman is preaching, as one of the board of lecturers of the First Church of Christ Scientists, led thereto, as it would seem, by a belief that Christian Science had cured him of asthma, and therefore that its droll theories are all facts. Need I recall your former *confrère* of this city, Dr. Dexter, and that worthy judge of our supreme court associated with him, Edmonds, whose book, full of recent letters from Lord Bacon, contained also appreciative communications from persons who, sentenced to death by the judge, returned to thank him for the kindness and consideration with which he had performed that somewhat unpleasant duty. Need I suggest that to-day keen and trained intelligences are declaring that from an obscure woman of Boston they are receiving absolute demonstrations of immortality, by events strikingly similar to those with which other wanderers in the same region have familiarized us? Certainly a theory, especially if it promises to make its promulgator a shining figure in the ranks of time, does wonderfully influence the power to observe facts. We believed myopic Zöllner when he told us of the distant stars; but we doubted when he said he saw Slade tie knots in endless chains, push articles of matter through a material table, and thus afford evidences in support of the great epoch-making discovery that there is a fourth dimension in space.

At the fountain-head of our difficulties with expert testimony lie fundamental sources of error and uncertainty. No consideration of remedies is adequate that disregards them. Discussing the matter we wander among paradoxes. Shall we accept the expert's conclusion or the jury's verdict? Shall we go with the extremists who sometimes seem to travel in a circle—as did he who, starting to prove that only expert testimony was reliable, concluded that impostors and thaumaturgists preferred to be investigated by clergymen, physicians, and lawyers, rather than by laboring men and children—or shall we walk safely with our wise, conservative Horace, in the middle path?

# THE DIFFERENTIAL DIAGNOSIS BETWEEN CHRONIC JOINT DISEASE AND TRAUMATIC NEUROSES.[1]

By REGINALD H. SAYRE, M.D.,

NEW YORK.

Those who have had extensive experience with disease of joints realize how difficult it is at times to decide whether or not a joint is involved when the symptoms of inflammation are just beginning to make themselves manifest, and that frequently several examinations of the patient may be necessary before an exact diagnosis is arrived at. They also realize how frequently such cases are treated for rheumatism, growing pains, and neuralgia for months before the deformity becomes so prominent as to force the true nature of the disease upon the observer. It is usually supposed, however, that after deformity and disability have taken place the picture is so marked as to make it impossible to fall into error, and that such cases need only to be seen in order to be recognized.

My experience, however, leads me to differ from this view, as I find certain cases in which there is no joint inflammation present symptoms so nearly approaching those of arthritis that they have been treated by men of large experience as if the joints were involved. I believe these mistakes in diagnosis are usually caused by failure to get the complete history of the case in the first place, by too superficial examination in the second, the patient's clothing not being sufficiently removed to enable the physician to make a proper investigation; and third, by a lack of attention to minor symptoms which, properly interpreted, would prevent the observer from reaching an erroneous conclusion.

Many cases of injury are followed by pains and disorders of the nervous system, and this not only in instances when the injury has been caused by a railroad accident, or been received in consequence of the carelessness of some person who can be held responsible for the damage, but when the patient alone is to blame and the possibility of legal redress does not enter into the question. That a traumatic neuritis is set up in these cases there can be no doubt, and the variety of neurotic complications that may follow such an injury is most surprising. At times also there are neurotic disturbances, the result of misplacement of the viscera, which may be classed as traumatic neuroses, though the trauma is merely that of abnormal pressure on a nerve or an abnormal stretching of its fibres.

In many of these cases, among symptoms that are present are pain in the neighborhood of a joint, accompanied by a limitation of motion in the joint, and more or less marked deformity, the physician being called upon to determine the nature of the disturbance which has given rise to these symptoms.

Has the patient Pott's disease or not? Has there been a fracture of the vertebra, or is tuberculosis or malignant disease of the spine present, or is the difficulty simply a neuritis set up by a traumatism and aggravated perhaps by inherited tendencies, a rheumatic diathesis, or an exhausted state of the nervous system? Are the atrophy and disability and distortion of a limb the result of hip disease or not? Does a patient require rest and protection for the joint, or should vigorous exercise be prescribed? These problems are extremely difficult to answer, and in many instances can be answered correctly only by the most careful and thorough examination of the patient's previous and present condition, taking into account the history of the case and noting on more than one occasion the attitude of the patient, the location of the pain, the presence or absence of muscular spasm, the range of temperature for several days and at different times in the day, the presence of motor or sensory disturbances in other parts of the body, and finally by taking careful note of the patient's mental condition.

One of the distinguishing points between a nerve inflammation and an inflamed joint is the rapidity with which symptoms of an injury to a nerve follow the trauma which produced it, while it may be months after the injury that manifestations of joint inflammation are marked enough to attract attention. While atrophy is a prominent and constant symptom in chronic inflammation of the joint, and makes its appearance usually before pain is at all pronounced in its character, yet it does not follow the onset of a marked traumatism so speedily as in the case of injury to a nerve.

Another of the most important factors in discriminating between a traumatic neurosis and a chronic inflammation of a joint, is the subnormal temperature that is usually present in the former, just as it is in various diseases accompanied by marked depression of the vital forces. There seems to be a lowering in tone throughout the entire system, with a corresponding decrease in the body heat. In chronic inflammation of a joint, however, there is usually a slight increase in temperature, say to 99° F., and one of the best guides to the activity of the destructive process going on in the bone is found in the reading of the thermometer. The local temperature also is apt to be much depressed after an injury to the nerve supplying this part, and at times an extremity or a part of an extremity will show a lowering in the surface temperature of one or two degrees below that of its fellow, or of other parts of the body. On the contrary, if an inflamed joint be at all near the surface, the increase in its temperature is usually sufficient to be detected by the touch, should a surface thermometer not be at hand. I would draw attention here to the fact that we may have a lowering of surface temperature in an extremity which has been kept at rest for a long time, either in bed or in a splint, while a joint in this extremity, as the knee or ankle, for instance, shows a marked increase of heat, and this distinction must be kept in mind in making a diagnosis between these cases and those of local subnormal temperature due to nerve involvement.

One of the early, probably the very first, symptoms of an inflamed joint is involuntary spasm of the muscles controlling that joint, and as the disease goes on this spasm becomes more and more pronounced. One of the peculiarities of this spasm is that passive motion within a certain limited range may often be made with entire absence of pain or resistance, while efforts at voluntary motion on the part of a patient, or motion greater in extent than that which the severity of the inflammation permits, at once excites muscular spasm and gives the appearance of complete ankylosis. Nature does not oppose motion of a joint so long as that motion fails to inflict injury, but as soon as it begins to cause irritation the muscles that control the joint at once spring into action in their effort to relieve and prevent the pain which is caused by the motion. If an anæsthetic is given in such a case the sensibility of the nerves is destroyed, and the muscles in consequence fail to control the movements of the joint, because they are no longer stimulated, and the physician is hereby deprived of the very symptom which would have been of vital importance to him had he made use of it intelligently. In many so-called "hysterical joints," and in these neurotic cases of which I speak, there may be a simulation of ankylosis and of muscular spasm, but careful observation will usually enable the physician to distinguish this from the true spasm of joint disease. By engaging the attention of the patient in other things and noticing the position of

[1] Read before the New York State Medical Association, October 26, 1899.

the joints meanwhile, motions will often be observed in joints supposed to be ankylosed. At times the patient may be induced to move the joint by placing the body in a different position from that in which the movement has usually been attempted, and then attempting to secure motion of some other joint, the movement of which will act on the joint under examination, the patient meanwhile having the attention concentrated on efforts to move the other joint, about which there is no question as to the diagnosis.

In cases of joint injury the location of the pain is to be borne in mind, and it may be a help toward excluding joint disease if the patient locates the pain in different places at different times, and at points other than those where the nerves supplying the affected joint should come to the surface. In spinal cases a tenderness along the whole length of the spinal column is almost proof in itself that the case is neurotic and not ostitic, the pain of bone inflammation being almost always confined to the distal extremities of the spinal nerves; or if the pain is felt in the back, it is only in a limited area. Should the patient be awakened at night, especially just as he is dozing off to sleep, by sharp pains that cause a loud, sudden cry, it is almost certain that inflammation of bone is present. The general appearance of the patient will often aid greatly in eliminating bone inflammation. The expression of certain neurotics can hardly be described, but, their appearance once recognized, the picture is as typical as the expression of melancholia or mania.

In some neurotic cases there will be found a peculiar œdema of an extremity which, being associated with great tenderness, may give rise to the supposition that a bone abscess is present, but a distinction can generally be made by the observation that the pain is not so localized as in a bone abscess, and extends frequently along the course of some nerve, and may at times be accompanied by nodosities of this nerve, changes in the color of the skin, purple or blue spots which may be elevated, and at times by patches which are very painful.

The histories of several of the cases that have fallen under my observation show how difficult it is at times to make a differential diagnosis between these diseases, and I will therefore briefly review a few of them:

Case I.—Last summer a girl of about twenty years of age was referred to me by a colleague at Bellevue Hospital for diagnosis and treatment. She was supposed to be suffering from hip-joint disease, and was wearing a long traction splint at the time of her admission. Her right thigh was flexed at about 45°, and adducted so that it crossed the left about half-way between the hip and knee, and was said to be ankylosed. The patient had been confined to bed for months. The question was whether or not an excision would be necessary to enable her to walk. On questioning the girl I noticed a curious expression which is often found in neurotic individuals, as well as a peculiar hesitating and deliberate speech which put me on my guard for something besides an inflamed joint. On asking her where her pain was, I noticed that when indicating the place she moved the affected limb under the bed-clothes, which I had purposely refrained from removing. On turning down the bedclothes and examining the limbs, the right hip joint was apparently firmly ankylosed in the position of flexion and adduction I have described; but as I examined it I managed to tickle her, and found that there was a sudden movement in the hip joint unaccompanied by pain. The right knee was bent and the hamstrings much contracted. The right ankle was in a position of equinus so marked that the dorsum of the foot was almost in a line with the shin. The foot was cold, and no motion of the toes or foot could be provoked by tickling or pricking. Examination showed the head of the femur to be in the acetabulum, and the trochanter in its proper relation to Nélaton's line. The patient complained of intense pain on efforts being made to move the hip joint, but her face and the accent of her voice caused me to think there was but little real discomfort. She also complained of pain over the bladder and lower abdominal region generally on palpation. The trunk seemed so curiously twisted as she lay in bed that I suspended her by the arms in a suspension swing, allowing part of her weight to rest on the sound foot, when I discovered a marked rotary lateral curvature of the spine, the patient complaining bitterly of any efforts to correct the latter, but always in a tone that to my mind precluded the possibility of her suffering real pain from the manipulations. I found that two years previously she had jumped from a second-story window and fallen between a wall and a house in a narrow space, and been violently bruised about the buttocks. For several days she had kept at work till the pain was so great that she was obliged to go to bed. She was then sent to a hospital, where a diagnosis of hip disease was made and a hip splint applied, which she wore for about a year. Later on she was admitted to Bellevue with the right thigh flexed and adducted, and was put to bed for several months with weight and pulley attached to her leg, without any improvement of position or relief of the pain from which she apparently suffered. Her temperature had not been elevated.

My diagnosis was a traumatic neuritis of the sciatic nerve, with subsequent deformity of the hip, knee, ankle, and trunk, probably from old synovitis, accompanied by contraction of many muscles and by fibrous adhesions in the joints. Under ether the adductor tendons were slowly stretched and the adhesions of the capsule of the hip joint broken up. The knee was also straightened by stretching. The tendo Achillis was divided subcutaneously and the foot put at a right angle with the leg. The patient's entire right lower extremity and trunk were then enveloped in plaster-of-Paris bandages, the right thigh being in a position of extreme abduction. For two or three days the patient complained bitterly of pain in her back caused by her position, but after that was perfectly easy. In two weeks she could move the toes, and on being removed from the plaster-of-Paris cast six weeks after the operation she could move the foot a trifle. Faradism was then given daily to the entire limb, together with gentle frictions and passive motions, and after a week the patient was encouraged to make active motions of her joints, under supervision. On noting a tendency for the adduction of the hip to recur, I placed her legs in the position of extreme abduction, and told her that unless she kept them in this position all the time I would be obliged to reapply the plaster-of-Paris cast. After this there was no tendency toward adduction. As soon as the muscles of the legs were a little stronger the patient was compelled to walk with crutches, and in less than a month could go all over the hospital without crutch or cane, having full motion of all her joints and good position of her trunk. At one time during her convalescence I was absent for ten days, and found on my return that the patient, who was just beginning to walk, since being free from strict control had assumed many of her old attitudes. I spoke very sharply to her, and found at my next visit that she had improved materially, and after that she made steady progress until she left the hospital.

Case II.—In 1897 a woman of about thirty years of age was put under my care at Bellevue by a colleague. She was employed in a factory where she ran a machine which required her to stamp violently with her left foot whenever the treadle was pushed, and to this she attributed her trouble. A couple of years before

coming under my observation she commenced having pain in the left knee, and shortly afterward a dark purple spot made its appearance on the inner aspect of the joint where the pain had been. She said this spot had swollen, grown darker in color, and finally the skin had peeled off, leaving a raw surface that had been slow to heal. She had visited one of the hospitals of this city and her knee had there been opened, but nothing being found the joint had been closed. The pain not diminishing after the operation, but extending along the upper part of the tibia, and being accompanied by some œdema, she was advised that in all probability she had an abscess in the bone, and an exploratory trephining of the tibia was advised. Not being willing to submit, she was discharged from the hospital, but, being unable to work, she applied for admission to Bellevue. She had visited an *x*-ray studio in the mean while and had two skiagraphs taken of the knee. These she showed to me when I first saw her, but they failed to disclose anything abnormal in the bones of either thigh or leg. When she first came under my observation she had been confined to bed for some months. The left lower extremity was somewhat shrunken and flabby and colder than its fellow, except at a spot one inch by three on the inner side of the knee, which was raised perhaps an eighth of an inch from the surrounding skin and purple in color. The slightest pressure on this spot seemed to give great pain, which radiated up and down the limb along the course of the saphenous vein. The outlines of the knee joint were fairly normal, but any movement of it was said to be attended by great pain. The skin over the tibia was œdematous, and pressure here was also very painful. As in the preceding case, however, the patient's voice did not to my mind indicate actual pain. The temperature during her stay in the hospital had varied, now and then running up to 102° F. with a rapid pulse, and again being subnormal. The purple spots appeared, she stated, after the pain had been very intense in this location for several days, and after lasting some weeks they would disappear, leaving no traces. Sometimes they appeared at the same time as menstruation, and the pain in the leg was always aggravated at this time. Menstruation was regular, but very scanty and accompanied by great pain before the flow began, this pain being in the pelvis and reaching around toward the buttock, whence it ran down the inner and posterior aspect of the thigh. There was also marked tenderness along the spine and between the shoulders, aggravated by the use of her arms. The extremities were cyanotic, cold, and damp. The pulse was rapid and feeble. These symptoms seemed to me so at variance with chronic inflammation of the knee that I concluded the pain was reflex in its character, and due to irritation of her pelvic nerves, probably in consequence of her occupation, added to natural inability to resist fatigue. Vaginal examination showed a very small uterus with a pin-hole cervix. This was stretched and the uterus faradized, with the result that menstruation became much more profuse and not attended by cramps and pain. The leg was wrapped in thick cotton and bandaged loosely, as tight bandaging caused a feeling as if the limb would burst. Motion in the knee was prevented by a splint, and the patient was put on crutches. Digitalis and nux vomica were given in compound tincture of cinchona. After two months the conditions had improved so that pressure could be made on the foot without causing pain, and the patient was gradually allowed to put her weight on her foot. The splint was removed daily and faradism and massage were gently applied. At various times the patient overexerted herself in various ways, and each time part of the old disability would reassert itself, but in the course of three months the splint was laid aside, then the crutches were abandoned, and little by little free motion returned to the knee. The patient can now walk four miles, but if she becomes overtaxed either physically or mentally the œdema and pain in the entire extremity recur to some extent.

Case III.—In June, 1888, Miss B——, aged twenty-six years, consulted me for supposed disease in the spine. She was a tall, fairly well-nourished girl, and gave a history of having fallen twelve years before, and of having pain and inability to walk gradually increasing since that time. At the time that she first consulted me her spine was markedly curved, but not with the usual sharp projection of spinal caries. She walked with great difficulty, complained of pain on the slightest jar, was unable to step without great pain, could not lie down or arise without aid, and when lying down was unable to turn over without assistance on account of pain. On rising from a chair she was obliged to put her hands on her knees to aid her. The left lower extremity was much smaller than the right, and sensation in it was markedly diminished. At this time she was wearing a plaster jacket, which had been applied by an eminent surgeon in this city. After careful examination of the case I came to the conclusion that, although there were marked pain around the abdomen, pains down the legs, very great sensitiveness on the slightest movement, and marked rigidity of the spinal muscles, her symptoms were more attributable to a uterine disturbance than to ostitis of the vertebræ, and I requested vaginal examination. I found the uterus markedly retroflexed and firmly bound down in the pelvis, and told her that when her uterus was replaced and held in its normal position, her symptoms would subside, and that I did not believe there was any disease of the vertebræ. It was not until some time after this that I learned from the patient her history, which she was very unwilling to give me at the beginning of the examination. About the age of fourteen years she had a fall, striking her right hip on the curbstone. She did not feel any effects for a few days, but afterward began to have pain on certain movements of the limb and body, when it seemed to "catch her," as she expressed it, and caused her intense pain. Several physicians examined her, thinking that she had displaced the joint, but found that it was sound. After about a year her feet began to swell, and the soles, particularly the heels, became sore, swollen, and painful. Then the left hip became affected as the right had been, and she was said to have sciatica, and for a number of years was obliged to use hypodermic injections of morphine to quiet the pain. The pain was worse while lying down, and often after going to bed she would be obliged to get up, and stand in a certain position for hours. Five years before the patient consulted me, her back began to ache. Three months after the onset of this symptom she went to Philadelphia and was examined by a very prominent physician, who pronounced it disease of the spine and ordered a leather jacket. Up to this time she had always been able to go about, and even walked quite well, but after the application of the jacket she became, as she describes it, perfectly "helpless," her arms becoming so weak that she could hardly lift them. Her physician then removed the jacket and advised her to remain in bed until the spine had become consolidated. This advice she did not follow, because she suffered so much pain while lying down that she was unable to do so. She then visited New York, and while here was seen by a professor in one of the colleges, who pronounced her trouble Pott's disease, and called another gentleman in consultation who agreed with him in diagnosis, and said that unless she would wear a support she would become humpbacked. He first applied a brace of his own, and, finding this gave no relief, applied a Taylor brace.

The latter failing to give comfort, he tried a plaster jacket, which she was enabled to "endure" for some three years. About this time the left lower extremity began to diminish in size. This history I did not learn from the patient until a number of months after first seeing her, her answers to my inquiries at that time being most vague and unsatisfactory. Having discovered the retroflexion of the uterus, I endeavored to replace the uterus and hold it in position by boroglyceride tampons, with some slight improvement. I then advised the patient to consult the late Dr. Lusk as to the advisability of performing "Alexander's operation" of shortening the round ligaments. This operation was performed by Dr. Lusk and held the uterus in very satisfactory position. The old pain in the back and legs began to diminish immediately after the operation, but the patient was restless and insisted upon going around too soon, and part of the old pain returned. As this pain persisted to some degree after the application of a suitable pessary, I attributed it to neuralgia of the sacral plexus and applied intra-pelvic galvanism with relief. I also directed the patient to take regular and systematic gymnastic exercise and massage to straighten her curved spine and relax the contracted muscles of the entire anterior part of her trunk. She speedily became more upright in carriage and has had steady diminution of her aches and pains. She wrote me under date of December 20, 1890:

"Since my operation I have never once felt the slightest return of those attacks in my hip I suffered with so long. I am quite straight and can keep myself up better. My health is excellent, and it would be impossible for me to tell you how well I am. I have neither ache nor pain. All troubles have vanished entirely. My muscular strength is much improved also."

The fact that all these cases presented symptoms so like those commonly associated with chronic disease of the spine, the hip, and the knee as to have caused various surgeons of experience to consider the bones involved, shows that the diagnosis was by no means clear, and I have gone somewhat into detail in the recital of these histories, as it seemed to me that they were worth careful study.

From the numerous other cases that have come under my observation I would say that in taking a differential diagnosis between chronic joint disease and a traumatic neurosis, the following points were chiefly to be noted:

1. A neurosis is apt to follow injury sooner than is disease of a joint.

2. The temperature is usually subnormal in a neurosis and elevated in inflammation of a joint.

3. The local temperature is usually much lower in case of a neurosis than in disease of a joint.

4. Atrophy progresses more rapidly after injury to a nerve.

5. True muscular spasm is not present except in joint disease. It may be simulated, however.

6. True night cries are pathognomonic of joint disease.

7. The appearance of the patient, if indicating a disordered nervous system, may aid in the diagnosis.

**Renal Hemorrhage.**—As a rule, renal hemorrhage from a neoplasm begins spontaneously, is unaccompanied by pain, and is uninfluenced by either movement or rest, ceasing suddenly without apparent cause, just as it began. It is apt to be more abundant than when caused by stone, and clots frequently form in the bladder. Its duration and the intervals between the hemorrhages are irregular. In some cases the bleeding may be occasioned by exercise and cease when the patient remains quiet.—W. K. Otis.

## Progress of Medical Science.

**Spasmodic Dysmenorrhœa.**—Morice, in discussing spasmodic dysmenorrhœa, states that it can exist aside from any lesion of the uterus or its appendages, whether congenital or acquired. This variety of dysmenorrhœa is related essentially to the different nervous or hysterical conditions of woman, whether they be acquired or hereditary, simple or tainted by the arthritic diathesis. It is found in young girls from puberty, and more often in women who have not borne children. It may be that this spasmodic condition of the uterus modifies the chances of conception, or it may be that it becomes itself the agent provocative of miscarriage. It is relieved by antispasmodic and soothing medication, and in cases of miscarriage by the mineral-water treatment.—*L'Abeille médicale.*

**The Glands of the Eye.**—Dr. Rohmer, of Nancy, in *L'Abeille médicale*, explains the physiological function of the glands of the eye as follows: The acinous glands of the conjunctiva are sufficient ordinarily to lubricate the eye and to maintain the moisture necessary for the functioning of the anterior membranes of the ball—the transparence of the cornea, and the protection and defence of both cornea and conjunctiva. When a reflex irritation, transient or even longer, occurs, of a psychical nature, *e.g.*, emotion, or a physical nature, *e.g.*, a foreign body, bright light, etc., the orbital gland secretes abundantly, and a flow of tears is established. In a word, the conjunctival glands are in a constant state of function, while the orbito-palpebral gland comes into play only on exceptional occasions, but which all the same may be relied upon to add its function.

**The Treatment of Gout.**—Luff (*Lancet*, November 18, 1899, p. 1361) lays down the following principles in the treatment of gout: In cases of acute gout the paroxysm must be treated and the severe pain relieved. This can be effected by free administration of colchicum and potassium citrate, and by a mild mercurial pill and sodium-sulphate purge. The painful joint or joints should be packed with wool saturated with a warm alkaline and anodyne lotion. The elimination of uric acid should be promoted. To this end free diuresis should be encouraged by the administration of plenty of water, and by the employment of potassium citrate or bicarbonate, or similar salts, which exercise a diuretic effect, and at the same time reduce the acidity of the urine. Green vegetable food should be taken freely for the same purpose. The excessive formation of uric acid should be checked. This object is mainly attained by a carefully selected dietary. When the acute attack of gout has subsided, butcher's meat need not be excluded from the dietary. On the contrary, it is better for most patients to partake moderately thereof. Although a mixed diet is best suited to gouty patients, it is important that the dietary should be a simple one, and it is especially desirable to avoid at any one meal much mixing of proteids and carbohydrates. The stomach of a gouty patient, unlike that of a healthy individual, is not well able to digest half a dozen different kinds of food at the same time. The metabolism of the liver should also be promoted by the administration of guaiac, and by an occasional mild cholagogue pill, and by keeping the bowels open. Attention should be paid to the general hygiene. Suitable exercise should be insisted upon as soon as the patient is fit for it. Enlarged joints and other gouty deposits should be treated with a view to the removal of the deposited sodium biurate. This can be accomplished in various ways. Massage and muscular movements increase the flow of lymph in

the lymph channels, and thus tend to promote the removal of uratic deposits, and to increase the metabolism of the joints. With this treatment passage of the constant current through, and the application of cataphoresis to, the affected joints and tissues may be combined advantageously. Baths of various kinds, including superheated air and radiant-heat baths, are valuable. Suitable treatment at a properly selected spa is also of great benefit.

**Treatment of Measles.**—In the *Revue des Maladies de l'Enfant*, Professor Grancher's treatment of measles is described by Vallat. Measles being diagnosed or even suspected, the child is placed in a soapy bath, followed by a bath of sublimate, in order to procure as perfect antisepsis of the skin as possible. At the same time all abrasions and eruptions are surgically dressed. Antisepsis of the superior respiratory passages is attained by the instillation of mentholated oil into each nostril. In order to make the alimentary canal as antiseptic as possible, a saline purgative is given in the beginning, and if constipation exists, an injection of boiled water is made into the intestine. In order to avoid bronchitis and broncho-pneumonia, the patients are bathed systematically according to the rules formulated by Renaut, of Lyons. This is exactly like the Brand method. Every three hours, night and day, the rectal temperature is taken. If it reaches 39° C., the child is put into a bath of 38° and left there from eight to ten minutes. The head is bound with a handkerchief, and if there is congestion, the vertex is wet during the entire bath with water at the temperature of the chamber. If the child is two or three years old, a little champagne or cognac and water are given. After the bath, the child is rapidly dried with hot linen cloths and put back to bed. Sooner or later, perhaps after the third or fourth bath, the fever falls and does not return. Sometimes, however, the temperature remains elevated three, four, or even five days. If, in spite of the baths, the catarrhal bronchitis becomes aggravated, or especially if a bronchitis develops, a little of the infusion of ipecac is given, from 30 to 80 cgm., according to the age of the child. It is well to add a little opium to relieve the cough. In case the patient is faint, a little ammonium acetate, to which is added a small quantity of benzoate of sodium, is given.

**The Tetany of Diseases of the Stomach.**—In the *Klinische Vorträge*, No. 254, Dr. Albu reviews this subject. Steinheim, in 1830, first called attention to this affection. Dance, Corvisart, Tonnelé, Trousseau, Kussmaul, Chvostek, and still later many others have added much to the knowledge of the subject. Tetany may be defined as the spontaneous occurrence of intermittent tonic muscle spasms of both sides of the body, especially in the hands and arms, depending on an excitability of the nerves of the affected muscle groups. The essential feature of this affection is the increased excitability of the nerves. This is shown as well for the galvanic as for the faradic current. There is also a mechanical nerve excitability which is most markedly seen in the region of the facial, and is called forth by tapping the nerve twigs with the percussion hammer, or by stroking them with the finger-nail. By pressure on the nerves in the bicipital groove, the writer's position of the hand is assumed, in which the thumb is pressed into the palm. This position is so characteristic of tetanus, that it alone, at times, is sufficient to make the diagnosis clear. The forearms are generally a little bent, and the upper arms adducted. The affected muscles are very hard and sensitive to pressure. The lower extremities are seldom involved. The convulsions are almost always symmetrical, generally lasting a few minutes, sometimes hours, more seldom for days. The interval between attacks varies from minutes to days. The diagnosis of tetany with visible spontaneous convulsions is easy, but must be differentiated from the tetanic, epileptic, and hysterical forms. The supersensibility of the nerves must be emphasized. The prognosis is always grave. As to the etiology of tetany, it varies to the greatest extent. There have been many theories. First, that of rheumatic influence was advanced. Much work has been done to prove the bacterial origin of this affection. The connection of tetany with the extirpation of goitre has been noted. For many years the occurrence of tetany in pregnant, parturient, and nursing women has been remarked. The most notable cases of tetany, however, have been connected with the various disturbances of the digestive tract, the most interesting being enlargement of the stomach. Fermentation naturally follows in its train. Three leading theories have been advanced to clear up this subject. The oldest is that of Kussmaul, who thought the cause of this affection to be concentration of the blood in consequence of the abstraction of water from the organism. This idea has been given up for some time. The second theory suggests that tetany comes from reflex excitation of the nerve centres by the irritation of the nerves of the mucous membrane of the stomach. This explanation was originated by Germain Sée and was upheld by Fr. Müller. Since Trousseau, tetany has been considered in almost all text-books under the head of neuroses. Later, when it was proved to be an infection or intoxication, it was taken from this group. Authors differ as to whether it is an affection of the central or peripheral nervous system. The third theory considers tetany as the consequence of abnormal changes of the contents of the digestive canal. Gerhardt, followed by many others, was the first to embrace this explanation of the disease. After all, however, the intoxication theory seems the most probable. There has been much experimental work in relation to this theory, but an absolute proof does not yet exist. Finally, the discovery of indicanuria, acetonuria, and diaceturia stands as clinical proof for the existence of abnormal changes of material in the intestinal tract. Weight is also given to this theory from the fact that other forms of tetany, especially that of goitre, are caused by the evolution of poison. As to the therapy of tetany, there is no remedy which can either stop an attack or prevent a recurrence.

**Poisonous Effects of Filix Mas and Their Prevention.**—Dr. Grawitz (*Deutsche Medizinal-Zeitung*, October 30th) says that the best-known injurious action of the drug is its poisonous effect upon the nervous system. Besides such mild symptoms as nausea, vertigo, syncope, and tremor, there occur severe convulsions, absolute unconsciousness, and delirium, which eventually may terminate in coma and death. In many instances the blood is so altered as to destroy the red blood cells by the absorption of the poisonous property of the ethereal extract, with the subsequent deposit in the liver, thickening of the bile, and production of icterus. Not infrequently, as the result of treatment by filix mas, gastro-intestinal catarrh occurs. In otherwise healthy persons, inflammatory symptoms on the part of the kidneys are rare. If, however, old inflammatory conditions exist in the renal organs then the ethereal extract might very well cause an increase in the symptoms and pathological condition. The same applies to the liver. From the foregoing experience it may be concluded that the large doses of 20 gm. and over, as formerly given, are very unsafe, and that in adults 8–10 gm., and in children aged over six years, half that amount, are the proper doses. In using the drug all laxatives, oils, and oily vehicles, particularly

the much-used castor oil, are to be avoided, inasmuch as the poisonous acid of the extract is very easily absorbed by oily substances. The most important conclusion of the toxicological examinations seems to be the observation that every weakness of any special organ, *e.g.*, liver and kidney, and that every general lack of resistance on the part of the entire organism increase the danger of a local or generalized poisonous effect. In the treatment of ordinary tapeworm the drug should be given only for therapeutic and not for diagnostic purposes. Before undertaking to expel the worm everything which tends to weaken the patient must be guarded against. It must always be kept in mind that the tænia produce a series of nervous and intestinal disturbances, and in many instances, on account of diminished assimilation, emaciation and anæmia. Even robust people after a long siege by the worm feel a marked weakness of the nervous and general system. It may be, therefore, that in many cases the preliminary treatment, with its weakening tendency upon the nervous system, may influence the occurrence of cerebral poisonous symptoms. On account of this possibility due to rigorous fasting and purging before the expulsion, the preliminary course of treatment has been omitted for many years. The day before expulsion the patients take their usual meals. On the morning of expulsion they receive Carlsbad or Epsom salts upon an empty stomach, and after a movement of the bowel the drug is given with coffee. In some instances even the laxative is omitted.

**The Diagnosis of Typhoid Fever.**—In a discussion of typhoid fever Dr. William Osler states (*New York Medical Journal*, November 4th) that there are no two or three symptoms characteristic of the disease. The hard-worked practitioners of country districts, in which the disease is now more prevalent, must rely in great measure on experience and common sense, and to them he says: "Learn to suspect typhoid fever and not malaria, in every case of fever of six or seven days' duration, particularly if it resists the action of quinine. For too long you have employed the Anglo-Saxon method of procedure, and in a given case have assumed innocence of anything so serious as typhoid until in the onset of some serious symptom the guilt was only too evident! It is high time now that you adopt the Gallic usage, and regard every case of continued fever as guilty, that is, as a typhoid, until the contrary be clearly demonstrated."

**Thrombosis in Chlorosis.**—This comparatively rare condition is described in four cases by H. Schweizer (*Virchow's Archiv*, vol. cliii., No. 2, 1899), with a *resumé* of the fifty-one previously reported cases in literature. The most potent cause, according to the author's investigations, for the thrombotic formation is a fatty degeneration of the intima of the blood-vessels. Influences which are particularly hurtful to the chlorotic patient seem to be poor food, confinement for a long time in badly ventilated rooms, and continued hard manual labor. The comparative frequency of the thrombosis formation shows high figures for the extremities, about seventy-four per cent.; twenty-four per cent. occur in one of the brain sinuses. One case is reported of thrombosis of the pulmonary artery. Thromboses in the brain sinuses are usually fatal, while the mortality for those occurring in the extremities reaches about twenty-five per cent.

**Serum Treatment in Typhoid Fever.**—In an article in *L'Union médicale de Canada* for October, 1899, Dr. Lesage reviews the history of the serum treatment of typhoid fever. In 1888, Chantemesse and Widal gave to mice repeated injections of bouillon typhoid cultures sterilized by filtration. In 1891 Briegner, Kitasato, and Wassermann, and in 1892 Bitter, instead of filtering the cultures, extracted by means of alcohol an active principle, their cultures being concentrated and heated to 80° C. In 1892 Sanarelli and Bruschettini sterilized their cultures by heating them to 120°. All these experiments demonstrated that the serum of animals which have been inoculated with the typhoid cultures possesses both preventive and curative properties as regards typhoid fever. The serum may be injected before or after the typhoid virus, the whole secret being in the dose administered. If, for example, the serum and virus are injected at the same place and time, half a cubic centimetre will suffice. If, however, the serum is injected before or after the virus, and at a different point, about two cubic centimetres would be necessary. About this same time, Stern and Chantemesse and Widal, experimenting with the blood serum of individuals who had already had typhoid fever, proved that its efficacy diminished proportionally to the length of time between the two injections. They also discovered that the serum of individuals who had never had typhoid fever was in certain cases endowed with immunizing properties. In 1895, Beumer and Peiper immunized sheep with typhoid cultures sterilized by a temperature of 55° to 60°, and obtained a very active serum. Finally, in 1896, Loeffler and Abel were successful in immunizing goats against the infection of the typhoid and of the colon bacillus, by means of the same kind of serum. Although the experiments of Chantemesse and Widal in 1892 and 1893 were unsuccessful, their later efforts were more satisfactory. The lack of success was thought due to the fact that experiments in the serum treatment of typhoid fever were made by the aid of serum of animals immunized against the colon bacillus. A report was made at the Congress of Rome in 1894, by Demel and Orlandi, who had obtained some favorable results by these means. Cultures of the bacillus pyocyaneus were employed by Presser in 1895, with mediocre results. Rumpf at the same time made the same trial with the bacillus pyocyaneus with similar outcome. He proved that cultures of this bacillus do not possess a specific power antagonistic to the typhoid bacillus, but act simply by exciting the natural means of defense of the organism. In the same year, 1895, Klemperer and Levy succeeded in augmenting the dog's natural immunity against the typhoid bacillus, by injecting into the peritoneum virulent cultures of Eberth's bacillus. They obtained in this way a serum so active that it would even bring about a cure if the injection was made a certain time after infection took place. Then with the same serum they treated five typhoid patients in the first seven days, and they all had an illness of the lightest character. It is easy to prove that the serum has not had any disagreeable effect. In 1899, Funck, of Brussels, obtained serum with curative properties from goats immunized by cultures of Eberth's bacillus, killed by phenic acid. Finally, in 1896, Chantemesse reported to the Society of Biology at Paris a serum taken from goats immunized against the toxin of the typhoid bacillus, of such power that one-fifth of a drop, injected twenty-four hours before the dose fatal for these animals, positively protected them against injurious effects of the virus. Following the example of Klemperer and Levy, he treated exclusively by this serum three patients ill with typhoid fever. In each case, the temperature gradually fell from the moment of injection, and "seven days after the treatment was begun, the patients were restored to normal temperature and to health" (Chantemesse). These results merit notice and are sufficient to inspire a hope that serum treatment may be found effective not only in typhoid fever, but also in other maladies now regarded as incurable.

New York, December 9, 1899.

## SANITATION OF STREET-CARS.

THERE was a time, and not so long ago either, when the New York electric street-cars bore an evil reputation for the manner in which they frequently ran down unwary pedestrians. Happily now, owing to improved brake machinery, which has given the drivers better control over their vehicles, the fatalities and injuries arising from this cause have been very considerably lessened. Still, even in this respect there is room for further improvement, and it seems decidedly curious that, taking into consideration the marvellous development of electric street-car service, and the peculiar aptitude of the American brain for invention, that a practical and efficient fender has not been produced. The fender now in vogue is to all intents and purposes as much a fraud as a safeguard. *Public Improvements* thus describes the ideal fender: "A fender should, in so far as possible, prevent injury to a person on the track of an electric car. It should prevent his getting under the wheels or under the car itself, and it should be so devised that the person will not receive injury from the fender itself either by being picked up or thrown against the front of the car. In order to prevent injury to the person it should have a resiliency or spring. And it should be so constructed as to retain its proximity to the ground despite the rocking of the car."

But it is rather with the internal economy of the New York street-car that we would deal. Locomotion on the surface lines in New York is fairly swift and punctuality is well observed, and as regards these two features, so essential to an American, the lines will compare favorably with the methods of transit employed in the majority of European towns. In the matter of comfort, however, there are many centres of population on the other side which can easily give points to New York. The cars here interiorly are for the most part commodious and comfortably upholstered and seated, and were it not for a serious drawback, which outweighs in the opinion of many all these manifold advantages, travelling in New York would be almost luxurious. But to the person who, owing to the calls of business, is compelled or who has occasion to make use of a New York street-car, at the time when the toilers are going to and from their work, the journey will decidedly not be one of unmixed pleasure, but, on the contrary, often a stern and hard struggle to gain even a footing, in which the weakest will go to the wall. Wedged in a seething mass of perspiring humanity, probably, if a delicate and well-dressed woman, jostled by workmen smeared and grimed with the effects of their day's labors, the end of the journey comes to the weary traveller as an immeasurable relief. This is a democratic land, in which, of course, a workman has as much right to use a street-car as a millionaire; but even the rights of democracy have their limits, and if regulations could be enforced to curtail the number of passengers to the seating capacity of the cars, the evil results of overcrowding would be avoided, and all classes of the community would be correspondingly benefited. This is a consummation that from the present outlook would seem to be more than problematical, nor until the public insist that efficient measures be devised to relieve the pressure put upon the existing means of transit can we hope for satisfactory reforms. We must e'en now take things as they are, while at the same time reserving to ourselves the privilege to protest and criticise and to suggest improvements.

The desiderata in a public conveyance are that it must be suited to the weather; in the winter warm and closed, but well ventilated, and in the summer open and airy. It should admit of being easily and quickly closed, and vice versa, and should at all times be as free from draughts as possible. As a writer in *Cassier's Magazine* says, "The car will not be satisfactory unless it can readily conform to the requirements of a season fickle at all times of the year." That the car does not now conform to these requirements is a proposition evident to all those who are in the custom of using this method of locomotion, and while freely allowing that so long as overcrowding is permitted to the extent it is, no effectual measures can be contrived which will bring it up to this standard, yet, if more attention were paid to some important details, the comfort of the passengers would be enhanced and their health would not suffer as is at present the case. For instance, there is room for considerable improvement in the ventilation system. In the winter there should be no necessity for opening windows for this purpose. These should be kept rigorously closed, and ventilation should be effected from the top. No passenger should be allowed to open a window at his own sweet will, thereby endangering the health of his fellow-travellers. Again, the doors should not be opened except when required to admit or let out a passenger, and in particular the doors at the end near the motorman should be always kept shut. Draughts are undoubtedly the cause of many a death.

The health board performed yeoman service when it interdicted the spitting nuisance in cars, and conductors should be impressed with the need of enforcing this healthful regulation. When the corporations controlling the railway service in New York are brought to realize that they cannot entirely ignore the health and comfort of their patrons, then and not till then will be evolved the model street-car.

The remedy, after all is said, lies in the hands of the people. The New York public is a long-suffer-

ing race, but even a worm will turn. If the inhabitants of New York will combine and persist in their efforts for the betterment of the existing modes of transit, the owners must eventually bow to their will.

---

## RINDERPEST AND HORSE SICKNESS IN SOUTH AFRICA, AND THE BRITISH ARMY TRANSPORT SERVICE.

Much stress has of late been laid upon the healthfulness of the South African climate. So far as man is concerned the salubrity of South Africa cannot be questioned, but for beasts of burden it is by no means an ideal land. Rinderpest is there more prevalent and more virulent than in any other part of the world. This disease is by far the most fatal known among horned cattle. According to a description in the London *Lancet*, "rinderpest is a specific, malignant, and highly contagious fever, characterized by acute inflammation of the mucous surfaces. It is spread only by communication direct or indirect from sick to healthy animals. It is essentially a bovine disease, though it may be communicated to other animals, especially to buffalo, and some of the antelopes in South Africa; sheep and goats are also liable to infection by the disease, but only to a slight extent." To furnish some idea of the fearful ravages wrought by this pestilence among cattle, Cape government statistics published in May, 1898, gave the total number of cattle in Cape Colony prior to the outbreak of rinderpest as 1,639,435. Of these 575,864 were destroyed, a percentage of a little over thirty-five. This wholesale destruction alarmed the British government, who sent out Koch to investigate the origin of rinderpest and to endeavor to find a cure or remedy. His researches were attended with a fair measure of success, and he produced an antitoxin which is said to have had the satisfactory result of checking the spread of the disease. Other investigators, notably Eddington, have improved upon Koch's serum. However, it is to be feared that the snake of rinderpest is but scotched, and not killed.

There is also another disease peculiar to South Africa which almost solely affects horses, although other members of the equine species are in a lesser degree liable to it. We refer to the South African horse sickness. This malady is of a most deadly nature, the mortality among horses in Natal in 1854–55 having been 64,850, while in 1892 13,979 horses succumbed to it. At one time it was believed that the disease was caused by insects, but later investigations have disproved this theory. Œdema mycosis, the technical term for the complaint, has, according to the most eminent authorities, no apparent connection with insects or surface wounds, but appears to depend, not upon conditions of the surface soil, but on temporary conditions of the vegetation which forms the pastures. Eddington thinks it is produced by a fungus which remains passive under the influence of dry air and is killed by prolonged drought, frost, and cold rains. This fungus forms abundantly during the night of a South African summer when much dew falls. It is stated that in the Cape Colony, Orange Free State, and Transvaal the disease rarely occurs before February, is worst in April, and like yellow fever disappears at the first touch of frost. In Natal it generally begins just before Christmas along the sea-coast. The disease, according to Hayes, occurs chiefly among animals which are allowed to graze while the dew is on the grass, and the growth of the microbe is supposed to be connected with the dampness of the grass. The disease contracted is almost always fatal, but the measures of prevention appear to be the folding of horses until the sun has dissipated the moisture of the dews. Horses are particularly liable to the complaint, mules much less so, while the humble but useful ass, which is, as is well known, a native of Africa, is wholly proof against the destructive microbe. With regard to what are termed salted animals, that is, those which have had the disease and are supposed to have become immune, opinions differ considerably. Many of the greatest veterinarian authorities hold that no immunity can be conferred by these means.

In view of the British military operations in South Africa these diseases may have an important bearing on the result of the war. The lines of railway available will not be nearly equal to the strain of transporting a tithe of the provisions required daily for the army of invasion, to say nothing of conveying the sick and wounded from the scene of action, and of sending to the front ammunition and other necessary military impedimenta. Therefore the greater part of the requisite traction power must be provided by animals. A very large quantity of mules have been purchased for this purpose by the British government, but the supply will yet fall far short of the demand, and the employment of trek-oxen must be perforce resorted to. If, unfortunately, rinderpest were to break out among these in epidemic form, it can be easily understood that the advance of the British troops would be much hampered and possibly entirely checked. Again, it is not unlikely, seeing that the time is approaching in Natal when the conditions favoring horse sickness are most in evidence, that the British cavalry and artillery horses may many of them be struck down by this disease. Taking everything into consideration, rinderpest and horse sickness may be destined to play a decisive rôle in the South African campaign.

---

## THE MOST SANGUINARY BATTLES OF THE PRESENT CENTURY.

The despatch from Lord Methuen to the Queen in reference to the battle at Modder River, in which he is reported to have said that it was the bloodiest one of the century, has occasioned a good deal of amusement in the United States. None of the papers believe that Lord Methuen said any such thing, unless, indeed, he spoke of the loss compared with the number of men engaged. The New York *Sun* makes the apposite remark that "as the number of Boers engaged was only about eight thousand, according to the British reports, and General Methuen is in command of only one division of the British army sent to the Transvaal, no battle between these forces could have

been the bloodiest of the century unless the slaughter of both armies was complete." In many of the New York journals a list is given of the bloodiest battles since the commencement of the year 1800. The New York *Sun's* list is as follows: "At the battle of Austerlitz in 1805, the French lost 7,000, and the killed and wounded of the allies numbered more than 300. The French losses at Bautzen in 1813 were 13,000, and at Wagram in 1809 they lost 18,000. At the Moscova on the retreat from Moscow they lost 30,000. At the battle of Leipsic in 1813, a three days' battle, the French losses were 65,000. More than 40,000 of the French perished on the field, altogether 80,000 being killed. At Waterloo the British lost 6,932, the French 28,850. In the last great attack on Sebastopol the French lost 1,646 killed and 4,500 wounded, and the English lost 385 killed and 1,886 wounded. At Plevna between 18,000 and 20,000 Russians were killed and wounded, the Turkish loss being about 5,000 less than the Russian. In the war between Prussia and Austria in 1866 the Prussians lost 9,172 and the Austrians 44,314 at Königgrätz. In the Franco-Prussian war, the Germans at Weissenburg-Worth lost 12,914 and the French 5,000 in killed and wounded. At Vionville-Mars la Tour, the Germans lost 15,799, or twenty-two per cent. of their army, the French loss being equally great. At Gravelotte, St. Privat, the German loss, according to a German authority, was 20,173. Another puts it at 25,000 and the French loss at 19,000.

"In the American civil war the aggregate losses at the battle of Stone's River were 13,249 on the Federal side and 10,266 on the Confederate side. At Gaines' Mill the North's aggregate loss was 6,837 and the South's 8,751. At Gettysburg the Union losses in killed were 3,070, wounded 14,497, and the Confederates 2,592 dead, 12,760 wounded. Chancellorsville, Union dead 1,606; wounded 9,762; Confederate, 1,665 and 9,081 respectively."

To this list might be added the battle of Solferino, in which perhaps a larger percentage of combatants was placed "hors de combat" than in any other fight within the century. Fourteen thousand Austrian soldiers were killed or wounded, and about the same number of the allied armies. Again, the battle of Omdurman deserves a place, for although the British troops suffered but slightly, the Dervishes at the lowest computation lost a third of their number.

---

**A Portrait of Dr. Metcalfe Presented to the Academy.**—Dr. T. Gaillard Thomas has presented to the New York Academy of Medicine a portrait of Dr. John T. Metcalfe, painted by Layams about twenty-five years ago. Dr. Metcalfe, now in his eighty-second year, has lived at Cold Spring on the Hudson since his retirement from practice in this city. His many pupils and admirers, who are now themselves entering the ranks of the "older practitioners," will most highly appreciate Dr. Thomas' gift, and will rejoice to see Dr. Metcalfe's kindly face added to the gallery of eminent physicians in the Academy.

## News of the Week.

**The Association of Acting Assistant Surgeons, United States Army,** was organized at a meeting held in the Seventh Regiment armory in this city on December 5th. The meeting was called by Major Azel Ames of Massachusetts and a number of the physicians who served as contract surgeons during the Spanish War. The main object of the association is to secure legislation from Congress looking to the carrying out of the promises made when their services were contracted for. They claim that many verbal promises were made to induce them to accept appointments as acting assistant surgeons. But when the time came to draw pay it was announced by the Treasury officials that the salaries of acting assistant surgeons were affected only by the act of Congress that provided for them the amount of $150 per month, that they were not entitled to extra pay provided by Congress for volunteer officers and enlisted men, because they were attached to no regular regiments. It appeared after the war that these officers were neither regulars nor volunteers, and the contracts and subsidiary agreements with the surgeon-general's department were practically annulled. The following officers were elected: *President*, Dr. Azel Ames; *Vice-Presidents*, Dr. Timothy Leary, Dr. A. R. Jarrett, Dr. T. B. Buffom; *Secretary*, Dr. J. P. Warbasse, of Brooklyn, N. Y.; *Treasurer*, Dr. Charles W. Brewer, *Historian*, Dr. W. S. Terriberry. A legislative committee was also elected.

**The Answer.**—"Can we diagnosticate obliteration of the receptaculum chyli?"—ANDREW H. SMITH, *M.D., in the* MEDICAL RECORD.

Why, certainly.—*The Sun.*

**A Fire at the Johns Hopkins.**—Dalton Hall, the chemical laboratory of the Johns Hopkins University, was seriously damaged by fire on Monday morning. It is estimated that the loss will amount to $12,000 or more. The upper story of the building was almost destroyed, and the lower floors were drenched. The chemical museum in the southwest wing of the first floor was ruined. The fire was discovered just beneath the private office of Professor Morse on the third floor.

**A New German Hospital.**—The new German Hospital in Williamsburg was formally opened Monday afternoon. It is at Stanhope Street and St. Nicholas Avenue, and was built through the efforts of the Plattdeutscher Volksfest Verein of Williamsburg. The institution has accommodations for several hundred patients. The house staff consists of Drs. L. Jacobowitsch, C. P. Freschbeier, Ernest Thun, and Edward Randall.

**New York Post-Graduate Medical School and Hospital.**—At the last faculty meeting of the New York Post-Graduate Medical School, held November 27th, Drs. R. T. Morris and S. Lloyd were made professors of surgery, and Dr. Max Einhorn professor of medicine.

**New York Graduates' Society of McGill University.**—The fourth annual dinner of the above society was held on Tuesday evening, November 28th, in the pink banquet room of the Hotel Majestic, Central Park West. The chair was taken by the president, the Rev. Dr. Edward H. Krans. The following were at the guests' table: Dr. George F. Shrady; Dr. J. A. Irwin, vice-president of the British Schools and University Club, New York; the Rev. Professor Bracq, of Vassar College, and Mr. A. Rives Hall, B.A., B.C.L., a delegate from the parent society in Montreal. The decorations were of flags and flowers. Back of the president's chair two large American and British flags were gracefully draped. On all the tables American, British, and German flags were grouped. An innovation this year was the presence of many ladies. They contributed to the evening's enjoyment by music and singing. The toasts were the President, the Queen, and the Governor-General of Canada. The toasts, "Old McGill," "The Founder," "First Principal and Benefactors" followed. The latter was proposed by Dr. Wolfred Nelson and eloquently responded to by the Rev. Dr. Krans. An affectionate tribute was paid to the sterling merits of the late Sir John William Dawson, whose death occurred this month. In speaking of the many benefactors to McGill, the gifts of Sir William McDonald were referred to. They amount to over $3,000,000, "and the end is not yet." "University Expansion and Influence in the Twentieth Century" was ably responded to by Dr. J. A. Irwin; "Sister Societies of McGill," by Mr. A. Rives Hall; "The Ladies," by Professor Bracq; "Our Guests," by Drs. George F. Shrady and George Wells. Dr. Shrady, in well chosen and felicitous phrase, said that he had been at all the banquets of the society, and that he felt himself a McGill man. "College Reminiscences" called out addresses from Dr. H. N. Vineberg, Dr. Meek, Mr. Gunn, and Mr. Harcourt Bull. The secretary, Dr. W. Ferguson, read letters of regret from a number. The officers elected on the evening of the dinners are as follows.: *President*, Rev. Dr. Edward H. Krans, M.A., LL.D.; *First Vice-President*, Dr. Wolfred Nelson, F.R.G.S.; *Second Vice-President*, Dr. James Albert Meek; *Third Vice-President*, Dr. Hiram N. Vineberg; *Secretary*, Dr. W. Ferguson; *Treasurer*, Mr. R. A. Gunn.

**St. Vincent's Hospital, New York.**—Drs. Charles H. Lewis and José M. Ferrer have been appointed visiting physicians to St. Vincent's Hospital.

**An Impersonator.**—Dr. Frederick Gutmann of this city writes to warn his colleagues against a man who represents himself to be Dr. Gutmann, and recounting a tale of misfortune solicits aid from physicians.

**The Plague** is reported to have appeared at Cadiz. Alarm has been caused in Japan by the occurrence of several cases of plague at Kobe. The disease was brought from China. Dr. Kitasato, the discoverer of the plague bacillus, has been placed at the head of the commission appointed to combat the disease. Another case of plague has developed in one of the crew of the ship *J. W. Taylor*, from Santos, which has been in quarantine for some time. Three other ships laden with coffee have since arrived at this port from Santos. All are detained at quarantine, and the health officials of this city refuse to admit any of their cargo. As the coffee in the four ships is valued at about one million dollars, the extreme caution of President Murphy of the health board became a serious matter. The absurdity of the law which insists that the chief of the health department of this city shall have no medical training or knowledge was never more clearly manifested.

**Leprosy in Guam.**—In a report to the Navy Department Lieutenant-Commander V. L. Cottman notes the existence of leprosy in the island of Guam, and makes some suggestions regarding its eradication. He holds that immunity in the island from this disease cannot be secured until all those who are suffering from it are isolated. Leprosy patients live now, he says, in the same houses with persons who are free from the malady, the natives being indifferent to its dangers.

**Diphtheria and the Schools.**—The public and parochial schools of Wellsville, Allegany County, N. Y., have been closed, owing to the prevalence of diphtheria. Several children have died and others are ill with diphtheria. At Glen Ridge, N. J., the board of health recently decided to close the primary department of the borough school on account of the prevalence of diphtheria. A number of new cases were reported, and the board decided that it would be wise to close the primary department for the present, at least. At Montclair, N. J., there has been contention between the board of health and the pastor of the Catholic church, caused by the board's determination to close the school in the latter's parish. Many cases of diphtheria had been reported among the children attending the parochial school, and the board, therefore, decided to suspend the sessions until the small epidemic had subsided. The priest, however, contended that the closure of his school, the public schools being open, was an unjust discrimination which was not warranted by the actual condition of the epidemic.

**Associated Health Authorities of New Jersey.**—At the annual meeting held at Mickleton on November 27th, Dr. W. F. Elgin, of Philadelphia, delivered an address on "Vaccine Lymph and its Production according to Modern Methods." Dr. Isaac Crowther, president of the Associated Health Authorities of Pennsylvania, presented a communication entitled "Contagious Diseases, and the Care and Duties Required of the Family and Others to Prevent their Spread."

**The Pay of Civilian Surgeons in the British Army.**—In reply to a question raised in the House of Commons, Mr. Wyndham said authority had been given to supplement the army medical staff in South Africa by the employment of fifty-six civilian surgeons and eleven nurses of the Army Nursing Service Reserve. The civilian surgeons would receive £1 a day with a horse and the allowances of a captain, and at

the conclusion of service they would be entitled to a gratuity of two months. The nurses would receive £40 a year with pay allowance, and a gratuity of £20 on the completion of their duties. The three consulting surgeons, MacCormac, Treves, and Makins, are to be paid at the rate of £5,000 a year.

**Philadelphia County Medical Society.**—At a stated meeting held November 22d a resolution was adopted on motion of Dr. J. Madison Taylor, recommending the appointment of one hundred and fifty medical inspectors with an annual salary of $300 each, for the purpose of making daily examinations of children in public, parochial, and private schools, under the auspices, authority, and supervision of the board of health and board of education. Dr. G. Hudson Makuen exhibited a case of pseudolalia in a boy of about thirteen, in whom systematic training, in conjunction with removal of pharyngeal adenoid tissue, had resulted in marked improvement in the speech defect. A second case of stammering was presented. In both hereditary predisposition existed. Dr. Henry Tucker made a report of a case of rheumatoid arthritis treated with hot air, and exhibited the patient, a young woman of about twenty-five years, in whom extraordinary improvement followed forty-five exposures to temperatures in the neighborhood of 250° F. in the course of three months. It is noteworthy that improvement did not set in until after the twelfth exposure. Dr. William S. Newcomet read a paper on "The Use of *X*-Rays in the Study of the Lung," and Dr. T. M. Tyson one on "The Practical Use of the Fluoroscope and Radiographs in Lung Diseases." Dr. H. B. Allyn presented a communication on "Dilatation of the Heart."

**Pathological Society of Philadelphia.**—At a stated meeting held November 23d, Dr. A. V. Meigs read a communication entitled "Morbid Cavities in the Liver," and exhibited illustrative microscopic sections. Dr. J. P. Arnold reported a case of sarcoma of the mediastinum, invading and destroying the middle and lower lobes of the right lung. Dr. Simon Flexner presented a communication on "Experimental Pancreatitis," exhibiting numerous gross and microscopic specimens. The lesions, interstitial, hemorrhagic, necrotic, and gangrenous, were induced by injection of various acids, hydrochloric and nitric, into the pancreatic ducts. Drs. W. S. Wadsworth and W. G. Spiller reported a case of tumor of the occipital lobe, presenting during life stellate degenerative changes in the retina like those associated with nephritis and attended with convulsions, although the growth was far beneath the cortex, invading the posterior horn of the lateral ventricle. Histologically it proved to be an alveolar sarcoma. Dr. J. P. Arnold presented several congenital anomalies in frogs—absence of one eye, a double anterior foot, and transposition of liver, heart, and spleen.

**Philadelphia Neurological Society.**—At a stated meeting held November 27th, Dr. F. X. Dercum exhibited a case of facial dystrophy in a well-nourished Russian woman, twenty-two years old, who presented atrophy and impaired activity of the muscles of the face, the greater on the left, without alteration in electrical reactions. Dr. W. G. Spiller exhibited a case of tabes dorsalis with preservation of the knee jerks in a woman, with optic atrophy, Argyll-Robertson pupils, lancinating pains, and slightly defective station and gait. Dr. F. Savary Pearce reported a case of melancholia cured by gynæcological operative suggestion, in a woman with uterine displacement and a delusion of pregnancy, in whom relief was afforded by curettage of the uterus. Dr. Pearce reported also a case of epileptic ambulatory automatism due to gastro-intestinal intoxication, occurring in a man with severe digestive derangement, and treatment directed to which exerted a restraining influence on the convulsive disorder. Dr. F. X. Dercum exhibited a case of cerebrospinal syphilis with unusual brachial palsy, occurring in a young colored man, who presented especially bilateral paralysis of the lower-arm type, with some involvement of the deltoids also. Dr. Wendell Reber exhibited a case of isolated abducens palsy, probably peripheral, occurring in a middle-aged woman, with a history of rheumatism and also of exposure to draught. Only the left external muscle appeared to be paralyzed, and improvement followed the administration of mercuric iodide, sodium salicylate, and potassium iodide, and local manipulation and applications of electricity. Dr. William G. Spiller reported a case of amyotrophic lateral sclerosis showing the extent of the motor cortex in man, in which he detailed the results of a most thorough and painstaking investigation, which disclosed tracts of degeneration from the sacral cord to the cerebral cortex passing through the corpus callosum. The study confirmed the localization of motor representation in the ascending frontal and ascending parietal convolutions. Marked pigmentation also was found in both cortical cells and cells of the anterior horns of the spinal cord.

**The State Sanatorium for Consumptives.**—The committee on sanitation for the State board of charities held a meeting in Rochester on Saturday last to get suggestions for a bill for the establishment of a sanatorium in the Adirondacks for the treatment of consumptives. Harvey W. Putnam, of Buffalo, and Dr. Enoch V. Stoddard, of Rochester, were present, but Dr. Stephen Smith of this city was absent. A number of physicians and others addressed the committee, and various opinions regarding the desirability of the proposed measure were expressed. One enthusiastic speaker said that the report of the sanitation committee, if it is put into legislation, will do more good in the State of New York than the work of all the charitable organizations for the next ten years. Another speaker, who was not enthusiastic at all, said that a sanatorium will merely set the pace, by spreading information throughout the State among the medical profession and among the people. As a home for incurables he did not see how the institution would benefit to any great extent. He had seen people cured of tuberculosis in western New York, he said, and they did not have to go to the Adirondacks or to Denver for it. He thought the establishment of sanatoria all over the State would be a benefit chiefly to the

politicians, whose lungs were in a very fair condition. The committee will report in favor of the establishment of a sanatorium, at the meeting of the State board of charites in this city on December 12th.

**Reading Notices** of proprietary articles have at last crept into the columns of one of New York's most conservative and hitherto proper medical journals. More's the pity!

**What Constitutes an Accident.**—A man died not long ago in Vermont in consequence of perforation of the intestine by sharp fragments of some indigestible material swallowed with the food. He was the holder of an accident policy insuring him, according to the usual formula, against "bodily injury sustained through external, violent, and accidental means." The company refused to pay on the ground that the cause of the man's death was not an accident, but the court has decided that this was an accidental injury within the meaning of the policy. In New York State it has been decided that the taking of poison by mistake is not an accident in the meaning of a similar insurance policy, but in Illinois the courts have ruled exactly the opposite.

**The Sectional Secretaries of the International Medical Congress.**—The executive committee of the International Medical Congress of 1900 has issued a notice that every one who desires to read a paper at the meeting must send the title and an abstract of his paper to the secretary of his section on or before May 1, 1900. The following is a list of the secretaries with their addresses in Paris: 1. Comparative Anatomy. Dr. Auguste Pettit, 6, Rue Saint André des Arts.—2. Descriptive Anatomy. Dr. Rieffel, 7, Rue de l'École de Médecine.—3. Histology and Embryology. Dr. Retterer and Dr. Loisel, 15, Rue de l'École de Médecine.—4. Physiology, Biological Physics and Chemistry. Dr. Dastre at the Sorbonne; Dr. Gley, 14, Rue Monsieur le Prince; Dr. Weiss, 20, Avenue Jules Janin.—5. General and Experimental Pathology. Dr. Charrin, 11, Avenue de l'Opéra; Dr. Roger, 4, Rue Perrault.—6. Pathological Anatomy, Dr. Letulle, 7, Rue de Magdebourg.—7. Internal Medicine. Dr. Rendu, 28, Rue de l'Université; Dr. F. Widal, 155, Boulevard Haussmann.—8. Medical Diseases of Children. Dr. Marfan, 30, Rue La Boétie.—9. Therapeutics. Dr. Gilbert, 27, Rue de Rome.—10. Pharmacology. Dr. Chassevant, 70, Rue de Rennes.—11. Materia Medica. Dr. Chassevant, 70, Rue de Rennes.—12. Neurology. Dr. P. Marie, 3, Rue Cambacérès.—13. Psychiatry. Dr. Ant. Ritti, the Charenton Asylum, Seine.—14. Dermatology and Syphilography. Dr. G. Thibierge, 7, Rue de Surène.—15. General Surgery. Dr. Walther, 21, Boulevard Haussmann.—16. Surgical Diseases of Children. Dr. A. Broca, 5, Rue de l'Université. Dr. Villemin, 58, Rue Notre Dame des Champs.—17. Urinary Surgery. Dr. Desnos, 31, Rue de Rome.—18. Ophthalmology. Dr. Parent, 26, Avenue de l'Opéra.—19. Laryngology and Rhinology. Dr. Lermoyez, 20 *bis*, Rue La Boétie.—20. Otology. Dr. Castex, 30, Avenue de Messine.—21. Stomatology. Dr. Ferrier, 39, Rue Boissy d'Anglais.—22. Obstetrics. Dr. A. Bar, 122, Rue La Boétie; Dr. Champetier de Ribes, 28, Rue de l'Université.—23. Gynæcology Dr. Hartmann, 4, Place Malesherbes.—24. Forensic Medicine. Dr. Motet, 161, Rue de Charonne; Dr. Thoinot, 8, Rue de l'Odéon.—25. Military Medicine and Surgery. Dr. Catteau, the Ministry of War. Paris.—26. Naval Medicine. Dr. Laugier, the Ministry of Marine, Paris.—27. Tropical Medicine. M. Kermorgant, the Colonial Ministry, Paris.

**Keeping Pigs in New York.**—Dr. Adami, of Montreal, in a biographical sketch of Sir William Roberts, recently published, remarks that there is "a rising young New York physician, known to many in Montreal, who upon the topmost story of one of the Madison Avenue palaces keeps and feeds, and ultimately analyzes a select herd of swine." A young New York physician who can afford not only to live in a "Madison Avenue palace," but to keep pigs there as well, is a rare bird and a lucky one.

**Inadequate Hospital Service.**—There is much complaint in Queens Borough of the insufficient hospital and ambulance service. The Jamaica Hospital is the only institution of the kind in the section, and it refuses to attend to accident cases beyond a radius of two miles from the hospital, and will not attend to medical cases without a physician's certificate as to the cause and nature of the disease. The hospital received $1,500 from the city this year, and a similar appropriation is made for the year 1900. On behalf of the hospital it is said that the appropriation received from the city is not half large enough, and that the money appropriated for this year was all used up by the 1st of July.

**Delicacies for the Sick.**—The New York Exchange for Women's Work calls attention to its Domestic Department, which will furnish all kinds of home-made delicacies for the sick at short notice. The Exchange is a charitable institution designed to help educated women in reduced circumstances, and is supported by voluntary contributions. Orders for invalids sent here are not only well filled, but the physicians who patronize the Exchange will be assisting one of our most worthy charities. The Exchange is at 334 Madison Avenue, corner of Forty-Third Street. The telephone number is 1226 Thirty-eighth Street.

**Navy Department,** Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending December 2, 1899. November 28th.—Passed Assistant Surgeon B. R. Ward ordered to the *Independence*, December 15th. Assistant Surgeon J. S. Taylor detached from the *Independence* December 15th, and ordered to the *Scindia* December 31st. Assistant Surgeon E. Davis appointed assistant surgeon November 21st. November 29th.—Surgeon G. P. Lumsden ordered to temporary duty on the *Franklin* December 1st, during absence of Passed Assistant Surgeon J. A. Guthrie, on leave; thence home and to wait orders. Passed Assistant Surgeon J. Stoughton, order of October 14th, detaching from the *Monadnock* and ordering

to the *Bennington*, revoked. Assistant Surgeon D. G. Beebe, order of October 14th, detaching from the *Bennington* and ordering to the *Ranger*, revoked.

**Smallpox.**—Two recruits suffering from varioloid arrived at Fort Slocum, David's Island, N. Y., from Birmingham, Ala., about two weeks ago. They were promptly isolated, as was the remainder of the detachment with which they came. The physician at the fort does not anticipate any spread of the disease. A quarantine against the island has been declared by the board of health of New Rochelle, and the children of the island will not be allowed to attend the New Rochelle schools for the present. Some excitement was created among the inmates of the girls' seminary of the Wesleyan University at Delaware, Ohio, by the discovery that one of the students was ill with smallpox. There were about three hundred boarders in the seminary, and over two hundred of them left for their homes at once. It is curious that vaccination, which affords such perfect immunity, should have greatly increased the dread of smallpox by making it an unfamiliar disease.

**General Leonard Wood** has been summoned to Washington from Santiago, and professional guessers are busying themselves as to the object of his recall. It is said on one hand that the President purposes appointing him civil governor of Cuba, while others think he was called home in order to give his opinion as to the advisability of instituting a civil government in the island at this time. Rumor also had it that he was to be rewarded by being appointed to succeed Dr. Sternberg as surgeon-general when the latter is retired by law. General Wood has, however, requested the newspapers to deny this story. He says that he has, it is true, served in the medical corps of the army, but has no desire to return to that branch of the service, and under no circumstances will he do so. The duties are pleasant enough, he says, but he has found another field more to his liking. Hereafter, he says, he will remain in the line of the army, and he does not care for a staff position.

**Obituary Notes.**—Dr. Adeline Martin Rea died at York, Pa., on November 23d, of pulmonary tuberculosis, at the age of twenty-seven years. She was graduated from the Woman's Medical College of Pennsylvania in 1893, and was a member of the York County Medical Society and of the Medical Society of the State of Pennsylvania.

Dr. J. P. Miller died at Oxford, Pa., on November 27th, at the age of sixty-three years.

Dr. J. H. Hassenplug died at Philadelphia on November 25th, of pneumonia, at the age of seventy-two years. He was graduated from Jefferson Medical College in 1850, and during the war was surgeon with the One Hundred and Ninth Pennsylvania Volunteers.

Dr. Frank West, of Baltimore, died in that city on November 16th, after a long illness. He was born in Maryland in 1851, and was graduated from the medical department of the University of Maryland in 1879.

Dr. Edgar Miles, one of the oldest practising physicians of Suffolk County, died at his home at Sag Harbor, L. I., on November 30th. He was seventy-five years old, and had practised in Sag Harbor and vicinity for fifty-five years.

Dr. Granville Brobst Slough died at his home in Easton, Pa., on November 27th, in the eighty-eighth year of his age. He was graduated in arts from Lafayette College, and in medicine from the Jefferson Medical College, in 1861. During the Civil War he served in the United States navy as a surgeon under Farragut.

Dr. John Stamford Sayre, formerly passed assistant surgeon in the United States navy, died on November 30th, at his home in Monticello, Mo. Dr. Sayre was born in Monticello August 7, 1857. He was graduated in arts from Princeton in 1878, and in medicine from the medical school of the University of Michigan in 1881. He entered the navy as assistant surgeon in 1884, and was assigned to the Asiatic Squadron, with which he remained until 1896. He was retired after attaining the rank of passed assistant surgeon, in 1897, on account of illness contracted while in the Far East.

Dr. Charles Edmund Jones, a homœopathic practitioner of Albany, N. Y., died on December 1st, in the fifty-first year of his age. He was a graduate of the Albany Medical College in 1872 and of the Homœopathic Medical College in this city in 1873.

Dr. William H. Kendrick, an eclectic practitioner in Indianapolis, died recently. During the Civil War he was on the medical staff of the army, and while stationed in Washington was attacked with pneumonia and apparently died. The body was about to be embalmed before being shipped to Indianapolis, when Dr. Kendrick suddenly returned to life. While unconscious he had visions of heaven, and always afterward believed that he had actually visited the celestial city.

Dr. Granville B. Slough died at Easton, Pa., on November 27th, at the age of sixty-one years. He was graduated from Jefferson Medical College in 1861, and during the Civil War was a surgeon in the United States navy.

Major Samuel T. Armstrong, surgeon of the Thirty-second Infantry, died on December 4th, at Manila, the cause of death being given in General Otis' telegram as leukæmia. Dr. Armstrong was born in Ohio, and was graduated from the St. Louis Medical College in the class of 1879. He was for some time a surgeon in the Marine-Hospital service, but resigned and entered into practice in this city. He was appointed brigade surgeon in the volunteer service from New York in June, 1898. He had been in the Philippines for some time. He was a member of the Academy of Medicine, the Pathological Society, the County Medical Society, the Society for the Relief of Widows and Orphans of Medical Men, and the Physicians' Mutual Aid Association.

Dr. Albert Fricke died at Philadelphia on November 17th, at the age of eighty-seven years. He was graduated from the medical department of the University of Pennsylvania in 1834, subsequently becoming resident and then visiting physician to the Pennsylvania Hospital. He was also at one time physician to the German Hospital.

### SECTION ON OBSTETRICS AND GYNÆCOLOGY.

*Stated Meeting, November 23, 1899.*

BROOKS H. WELLS, M.D., CHAIRMAN.

**Mistakes in Diagnosis of Appendicitis.**—DR. S. MARX presented a series of specimens illustrative of this subject. The first had been obtained from a woman, twenty-eight years of age, from whom he had removed a dermoid cyst two years ago. Convalescence had been normal. A year later she had developed what her physician had considered to be an acute attack of appendicitis, but had recovered without operation. She had had two or three similar attacks before he had been called to see her because of one of unusual severity. Immediate operation had been demanded, and on incising the abscess cavity and evacuating the pus he had found within the cavity a large silk ligature. No search had been made for the appendix because the cavity had been walled off. Healing had taken place quite rapidly. The second specimen had been removed at an interval operation for appendicitis. The patient was twenty-four years old, and had had numerous attacks previously, one of these having been diagnosticated by an eminent surgeon in the South as an attack of gall-stone colic. There had, however, been no jaundice, no gall stones had been found in the stools, and the pain had been associated with more or less fever. Palpation through the rectum had pointed to the appendix as the offending organ. During the operation the appendix had ruptured at the base. It had been tied off in the usual fashion, and recovery had been uneventful. The operation in this case had been that known as the Kammerer operation. The third specimen had been taken from a woman of thirty-one years, who had been well up to six weeks before. She had then begun to bleed rather irregularly, and this had been associated with a rise of temperature, a rapid pulse, and excruciating pain—indeed, all the symptoms at that time had pointed to a ruptured ectopic gestation. The attending physician had diagnosticated an appendicitis, and had advised operation, but it had been declined. At the time the operation had been agreed to and performed, the temperature had been 102° F. and the pulse 130. A ruptured ectopic gestation had been found on the right side, and removed. The patient had made a satisfactory recovery. The fourth specimen had been taken from a woman who had been married only three weeks, but who had been infected with gonorrhœa by her husband even in this short period. She had developed all the usual symptoms of an appendicitis. Suddenly her pulse had risen to 126, and the pain and rigidity in the appendical region had been typical. Vaginal examination had been negative. Operation had been refused, and, on the following day, much to his surprise, the pulse and temperature had fallen to normal. This had continued for three or four days, and then there had been a temperature of 101° F. and a pulse of 118. She had then submitted to an abdominal section. This had shown the source of the pus not to be the appendix, but a pus tube. The appendix had been reduced almost to a fibrous cord, although there was no history of a previous appendicitis. The cavity had been drained for five days. On the seventh day she had unexpectedly developed a pneumonia, which had terminated fatally in a short time. The fifth specimen had been removed from a woman who had been perfectly well previously. Her illness had begun with tenderness in the right iliac region and general abdominal pain. The pulse was 108 and the temperature 102° F., in the rectum. Examination per rectum had thrown some doubt on the diagnosis because of the high situation of the tumor. On opening the abdomen it had been ascertained that the tumor was retroperitoneal and that the appendix was perfectly normal. Back of the peritoneum free pus had been found, but the woman's condition had been such that he had sutured the peritoneum so as to wall off the pus. Two days later he had continued the operation, and had found, and removed, a suppurating kidney. She had developed an acute pneumonia, but in spite of this had made a good recovery. It was probable that this kidney had become infected at her confinement, at which time she had had some cystitis.

DR. LE ROY BROUN said that he had been rather surprised at the positiveness with which Dr. Marx had spoken of his ability to make a diagnosis of ectopic pregnancy merely from the history. Although he had personally had a fairly large experience with these cases, he felt that all diagnoses of ectopic pregnancy should be looked upon as tentative.

**Appendix on Left Side.**—DR. P. A. HARRIS said that in a certain percentage of cases of ruptured ectopic pregnancies there would be a rather marked elevation of temperature, just as had occurred in Dr. Marx's case. The speaker then reported a case in which there had been a transposition of the appendix. An appendix about five inches in length had been found in the left side of the abdomen, and owing to the short mesentery its tip could not be brought beyond the median line.

**A Case of Mild Sepsis Treated by Unguentum Credé.**—DR. S. MARX reported this case, which had surprised him because of the good result obtained. He had used this ointment, he said, in a number of other cases, but without observing any benefit therefrom. In this patient the highest temperature had been 102.5° F. and the highest pulse 120. The patient was a primipara in whom he had induced a premature birth at the sixth month because of a grave and rapidly increasing melancholia. On the third day the temperature had risen suddenly to 101.5° F., and nothing could be found to account for this temperature except two caked breasts. At this time the physical examination had been negative. On October 17th typical pseudo-diphtheritic patches had been found in the vagina and on the vulva and cervix. The parts had been thoroughly cauterized with pure carbolic acid, chloride of zinc, and solution of iron successively, but without result. The parts had then been irrigated very frequently, but there had been absolutely no improvement. Repeated chilly sensations had then been complained of. Having no faith in streptococcus serum, he had tried unguentum Credé. The ointment had been first used in the evening, and by the next morning there had been a decided improvement in the membranous patches. The ointment had been used every four hours for the first day. In seventy-two hours there had been no trace of the patches. The speaker said that he had never seen any such effect from other remedies.

DR. JOHN POLAK said that he had employed Credé's ointment a number of times, and the results had been extremely variable. In one case the result had been excellent, and was of the more significance because no other treatment had been employed. The case had been seen three weeks and a half after confinement. At the time the temperature had ranged between 102° and 103° F.; the uterus had already involuted fairly well, and there had been no membranous patches. After each application of the ointment the temperature had dropped one to one and a half degrees. The treatment had been continued for over a week, and

then the temperature had reached the normal and convalescence had been completely established. The case was one of late and persistent sepsis, in which the ordinary local treatment would not have been of value, in all probability. In two cases of post-operative sepsis in which he had employed this method of treatment he believed some benefit had been derived from the ointment, although he could not speak positively on this point.

Dr. S. S. Jones said that he had used the Credé ointment in a number of cases of miscarriage in which the fever and other symptoms had pointed to a mild sepsis, and in these the ointment had seemed to act admirably. He thought the case reported in his paper last year had shown at least one thing—that the ointment had acted very much like an antitoxin. He believed its use would save life.

Dr. Vineberg remarked that he had seen a young woman's life sacrificed by depending upon the unguentum Credé. Such an agent might perhaps be used by experienced physicians, but the trouble with methods of this kind was that the necessary discrimination was often lacking. For this reason the treatment involved the employment of a dangerous principle.

**Nephrectomy for Ascending Tuberculosis.**—Dr. Hiram N. Vineberg reported this case, and presented the patient. He said that in October, 1898, he had reported to that section a case of tuberculosis of the bladder that he had had under observation for ten months, and he had then promised to report later on it if anything of interest should develop. The patient was a woman of forty-seven years who had been suffering from painful and frequent micturition for six years before coming under his observation in 1897. There had been no hæmaturia so far as known. It was very rare indeed, Dr. Vineberg said, for a case of tuberculosis to be followed from the bladder up the ureter. He did not consider it a descending tuberculosis because when first seen there had been absolutely no renal symptoms, and both ureteral orifices had then been free. A few tubercle bacilli had been discovered in the urine. Under topical applications, made twice weekly, the bladder symptoms had improved considerably. At first there had been a patch of redness at some distance from the left ureteral orifice, but early in the present year this redness had extended to the ureteral orifice. In March he had removed the left kidney, the wound healing by primary union. Later a fistula had formed, and had not closed for three months. Since the operation this woman had gained fifteen pounds, but the bladder symptoms had remained about the same. When in the recumbent position the urine came in contact more with the reddened area, and this explained the irritation experienced at night. The kidney had been completely destroyed by a suppurative process—for the most part, a caseous tuberculosis. When the involvement of the kidney occurred rather early there would not be much enlargement of the organ, but the destructive process would be quite extensive.

**Acute Salpingo-Oöphoritis Complicated by Appendicitis and a General Peritonitis, Probably Gonorrhœal.**—Dr. Vineberg reported this case because there was a strong probability that the general peritonitis was of gonorrhœal origin. When first seen the woman had been suffering a great deal of pain; the temperature was 101° F., and the pulse 120, small and wiry. The abdomen was tender all over. The uterus corresponded in size to a pregnancy at the sixth week. Inquiry had elicited the fact that the husband had gonorrhœa and had recently had intercourse with his wife. The uterus was curetted and decidual membrane removed. Then the abdomen being opened an acute general peritonitis had been brought into view. The right tube and ovary were highly inflamed, and were extirpated. The appendix was buried in adhesions. The flakes of lymph had been rubbed off the intestinal coils and the abdominal cavity flushed with saline solution. Gauze drainage was used. Some of the flakes of lymph had been examined microscopically and bacteriologically, but with negative result. The peritoneum had been very acutely and intensely inflamed; so much so that he had despaired of the woman's recovery, though believing that the peritonitis was gonorrhœal. However, she was now thoroughly convalescent.

Dr. Le Roy Broun took exception to the statement that this case was probably one of peritonitis of gonorrhœal origin; he would rather consider it a septic peritonitis.

**Pregnancy Complicated by Sarcoma of the Kidney.**—Dr. Edward A. Ayers made this report. The patient, a woman of twenty-one years, had ceased menstruating on November 28, 1898. One month later she had noticed a fulness on the right side, which had increased more rapidly than had the size of the uterus. When the patieat was seen by him on June 25, 1899, the temperature had been 90° F. and the pulse 90, while the urine had contained a large quantity of blood. The patient was profoundly anæmic. The uterus was enlarged to a size corresponding to a seven months' gestation. There was a large, hard tumor behind and to the right of the uterus. The tumor was thought to be a cystic sarcoma of the ovary. It was evident that the pregnancy could not go to term for lack of room for the uterus, and the anæmia was so profound that he had favored the induction of premature labor. On July 20th this had been done, and she had been delivered of a fœtus weighing less than four pounds. Subsequently he had done an abdominal section upon her, and had found the transverse colon adherent to the lower part of the tumor. The latter had proved to be the right kidney. Severe hemorrhage had been excited during the separation of the adhesions, and in spite of saline infusion and the usual measures the patient died three hours later. The tumor had an average diameter of nine inches, and weighed seventeen pounds.

Dr. Marx said that this case reminded him of a similar one seen by him a short time ago—that of a multipara, thirty-six years of age, pregnant at the sixth month. His diagnosis had been hydramnios, and labor had been induced, but to his surprise he had found a tumor of the left lobe of the liver. He had then learned that a small "wart" had been removed from the woman's left side a short time before, and that it had quickly recurred.

**Atresia Vaginæ Complicating Labor, with Report of a Case.**—Dr. George Grey Ward, Jr., read a paper with this title. He stated that the most common form of atresia of the vagina was a soft septum, one-eighth to one-fourth of an inch in thickness, situated in the middle of the vagina, and having a small opening. The danger of such a condition depended entirely on the degree of obstruction. If the stricture was fibrous or cartilaginous, the gravest consequences might ensue, such as delivery of the child through the rectum. Rupture of the uterus had also occurred. The atresia might be congenital or acquired. The former was rare, and was due to cessation of development. The acquired form was usually the result of bad management in previous confinements. Inflammatory affections of the vagina complicating various diseases might also be etiological factors. The treatment must always be dependent upon the character of the barrier. A septum that appeared thick and unyielding in the early months of pregnancy often became soft and yielding at full term. According to Playfair, there was seldom any serious difficulty from atresia of the vagina, but the obstetri-

cian should remember that the unaided dilatation of this second cervix might prove exhausting and disastrous to the patient. Hydrostatic dilators would render valuable assistance, and slight nicking of the stricture would often materially assist the progress of labor. Cases had been reported showing that attempts at dilatation, even during the early months of pregnancy, were apt to be followed by abortion. In the light of modern obstetric surgery Cæsarean section would be considered proper in those cases in which the atresia was very great, in preference to craniotomy or embryotomy. Dr. Ward then reported a case in which there had been a septum, one-fourth of an inch thick, at the junction of the middle and upper thirds of the vagina. The septum had been soft, but it had materially reduced the depth of the vagina. Dilatation of this stricture had been practised last June, and early in July labor had set in. Then with digital dilatation, and the aid of the forceps, delivery had been effected, and the patient had made an uneventful recovery.

Dr. E. A. Ayers reported, in this connection, two cases of atresia. The first case was that of a woman having a constriction near the cervix, and an opening admitting a uterine sound. The anterior lip of the cervix was united to the cicatricial tissue up to the margin of the external os. She was suffering from hemorrhage, apparently as a result of cicatricial tissue in the endometrium. The atresia had been produced, in all probability, by the use of too strong an antiseptic. In the second case, the atresia had probably resulted from the use of a very strong vaginal douche after labor at a time when the parts had been very much relaxed. In a third case there had been a tight stricture, which had been incised, and an effort made to effect delivery. Failing in this, he had made the mistake of doing a symphyseotomy instead of a Cæsarean section. Infection of the wound had occurred, and had led to pneumonia and death.

Dr. P. A. Harris reported a case of complete atresia of the vagina attended by him nearly four years ago at the Paterson General Hospital. The woman had borne three or four children previously, and had been in labor at the time of his examination. This revealed a small sulcus where the vagina should have been. Even by palpation through the rectum he had not been able to detect the presence of a cervix. He had done a Porro operation and delivered a living child. She had made a good recovery. According to the history she had received douches and uterine treatment about ten months before, and had been very sore for a considerable time as a result of this treatment. It was probable that some strong antiseptic had been used in the douche, and had cauterized the vagina, and that the woman had gone home before healing had taken place, and had then become pregnant, the vagina subsequently becoming stenosed.

Dr. Vineberg thought the case was one of very tough hypertrophy of the hymen. He had seen just such a case not long ago. He favored excision of the annular stricture during pregnancy, and suturing the vaginal wall to prevent reclosure. In one case in which he had done this the result had been good.

Dr. J. J. E. Maher said that about ten years ago he had reported a case of atresia of the vagina. He had seen the woman one month before labor and had found along the posterior wall of the vagina an aperture 2.5 mm. in diameter. Dilatation had been effected with a hydrostatic dilator, and delivery easily effected with forceps. This case had led him to search the literature, with the result that he had collected records of one hundred such cases. In this series a membrane had existed in fifty-six, and a mere band in only twelve cases. Perhaps the most difficult point to decide was in regard to the thickness of the obstructing membrane. He had accomplished this in one instance by inserting a laminaria tent, and when it had swollen noting the size of the indentation made in it. In the series referred to there had been twenty-one different complications, such as hemorrhage, unusual presentations, and pelvic contraction. Notwithstanding this, only thirteen mothers and forty-one children had died.

**The Treatment of Cancer by Its Own Toxins.**—Dr. P. J. McCourt read this paper. He said that he had been led to prepare a serum for cancer, working on new lines. To obtain the primary serum he had selected a typical case of rapidly recurrent carcinoma, the patient being otherwise in good health. The ulcerated surface was cleansed without the use of antiseptics, and sterilized dressings were applied to the part for forty-eight hours. The virus was then collected by curettage and mixed with perfectly pure vegetable glycerin, after which it was triturated and separated by means of a special separator that he had devised. After the fifth trituration, micro-organisms could not be found, but nevertheless this serum was very virulent, and was not fit for use. By repeated subdivision and attenuation the toxins became antitoxins. Alcohol must not be employed in any step of the preparation; even a mixture with animal glycerin, of standard purity, had been sufficient to render the serum inert. The serum was administered by the stomach, two or three times a day, for a long time. Toxic symptoms would rarely follow a correct selection of the preparation and of the dose, but a critical erythema, closely resembling erysipelas, might occur. The subcutaneous administration of this serum had proved irritating and useless. A strict regimen, including absolute abstinence from alcohol, must be enjoined —even a single glass of beer was apt to neutralize the treatment of an entire month. A considerable number of cancer cases had been kindly referred to him from a number of the hospitals in this city. Some of the results of the treatment had been encouraging, but in a preliminary paper of this kind he preferred not to dwell upon the results. Even in the most advanced cases the antitoxin had been found to relieve pain, improve the general health, and retard the progress of the disease.

## NEW YORK COUNTY MEDICAL ASSOCIATION.

*Stated Meeting, November 20, 1899.*

Frederick Holme Wiggin, M.D., President.

**The Tonsils as Portals of Infection.**—Dr. Emil Mayer read a paper with this title. He stated that certain forms of infectious diseases followed closely upon tonsillar affection, the same micrococci existing in the former as in the latter, and hence, they being mentioned tonsillar in origin, was to-day an established fact. Chief among the list of affections thus originated stood rheumatism, many others being noted that were not infectious in their nature, such as albuminuria, erythema, urticaria, etc. One writer had reported four cases of angina pectoris, another a case of phlebitis, while still others mentioned pneumonia and pleurisy. All of these had been said to be of a tonsillar origin. In addition to the diseases enumerated, it had been shown quite lately that we must add endocarditis to the list. One such case, typical of the rest, was recorded. A young man aged eighteen years had died of general pyæmia consequent upon tonsillar affection. The autopsy had revealed broncho-pneumonia and deposits on the tips of the pulmonary valves. The staphylococcus aureus had been found there and in the white tonsillar exudate. To the five cases re-

ported by Packard the author added a case of endocarditis following tonsillitis of the follicular variety, that had come under his own observation. He said that, granting that we had established the etiological factors of some of the infectious diseases, it became our manifest duty to take such steps as would tend to the prevention of such infection. We should positively maintain that neither follicular tonsillitis nor peritonsillitis was the innocent affection we had hitherto classed it as being, and should treat these conditions energetically. In the early stages peritonsillitis might be aborted. After the angina had subsided, a very careful examination of the fauces should be made, and every bit of tonsillar tissue removed either with the tonsil punch or by tonsillectomy with the galvanocautery. Operative procedures must under no circumstances whatever take place while an acute process was going on. The author arrived at the following conclusions: (1) Infection arose in the tonsil; (2) tonsillar affections were frequently serious in their sequelæ, and every step to prevent recurrent attacks should be taken; (3) the existing tonsillar disease should be energetically treated; (4) careful examination and treatment were absolutely essential in the interim; (5) following anginas the heart and other organs should be examined from time to time.

**General Infection.**—Dr. Isaac Adler said that this subject did not seem to be sufficiently recognized by the profession at large. There was now abundant clinical and experimental proof of the fact that the lymphatic system opened directly into the tonsillar crypts, and that there was an interchange from the surface of the tonsils to the lymph current at all times—a continual transmigration of leucocytes more or less loaded with the refuse of metabolism and with bacteria directly into the lymphatic system, and secondarily into the blood current. It was also known that the crypts of the tonsils, even in health, were a common hiding-place for various bacteria. Of all the bacteria which made the tonsil a breeding-ground it was probable that the staphylococci and the streptococci were the ones which most easily entered the lymphatic system and the blood current. Whether a streptococcus pneumonia or a staphylococcus pneumonia could be directly produced by tonsillar inflammation seemed to him as yet in doubt. That angina pectoris itself was not caused by tonsillar infection he would state positively, and also that tuberculosis did not arise from such infection. He was sorry to see that many in the medical profession still believed that there was a distinct relation between tonsillar inflammation and articular and muscular rheumatism. There was every reason to believe that all forms of rheumatism, both acute and chronic, were nothing more than infections with attenuated pyogenic bacteria—principally the staphylococcus aureus and the streptococcus. It was easy to understand that inflammations of the tonsils might, in certain instances, result in rheumatic manifestations. It was not uncommon for a severe rheumatism to begin with a tonsillitis. A rheumatic endocarditis was not one produced by any diathesis, but simply an infection of the valves of the heart by the staphylococcus or the streptococcus, principally the latter. Myocarditis, as well as endocarditis, had been observed as a consequence of infection from the tonsil. He would go so far as to class the case of systolic murmur described by the reader of the paper as one of acute myocarditis following tonsillar infection. He fully concurred with the author of the paper in the statement that the tonsils once inflamed became a menace to the entire system, and that repeated inflammations of the tonsil were a source of great danger. For this reason, recurrent tonsillitis was a positive indication for the ablation of the tonsils.

**Endocardial Infection.**—Dr. Frederick A. Packard, of Philadelphia, presented the histories of five cases, already reported, and two others having a similar character. He said that his attention had been first called to the relation between true angina and endocarditis by an illness occurring in a boy whose heart he had frequently examined before, and found free from abnormalities. He had been called on December 25, 1893, to see this boy, and had found him suffering from tonsillar inflammation. The next day there had been, for the first time, a loud, rough systolic murmur. The tonsillitis had disappeared within a few days, but the murmur had persisted, and had been heard at an examination made two years later. There had not been in this boy the slightest manifestation of rheumatism. The second case was that of a girl aged thirteen years who had also been under his care for some time. In her, too, there had not been the slightest suspicion of rheumatism. In 1894 she had had an acute attack of erythematous angina, with which there had been a curious irregularity of the heart, and marked tachycardia. This attack had passed off rapidly, but convalescence had been rather slow. Repeated examinations of the heart afterward had failed to show any abnormality. Almost one year later she had had a severe attack of angina, apparently of the same form as before, and on the second day she had developed a loud, harsh systolic murmur, heard well at the apex, and transmitted to the left of the axillary line. He had examined her only a few days ago, and she had this murmur. The third case was that of a boy coming to the dispensary, a stranger to him. There had been at the time an acute angina, but on the third day a harsh murmur had developed at the apex of the heart, and one week later pericardial friction sounds had been heard, together with a systolic murmur. Within a few days of this the systolic murmur had disappeared, but a presystolic murmur had then become audible at the apex. The boy had not been seen since that time. The fourth case was that of a male adult, thirty-two years of age, and was interesting on account of its being an adult. The man had been seen in Dr. Musser's ward. He had had angina when first seen, and two harsh murmurs. A year or two afterward this same patient had been seen, and there had then been dilatation of the heart with loss of compensation. The fifth case had occurred in a boy with whose family he had been acquainted. The boy himself had been attended by Dr. L. A. Starr, who had assured him that there had been previously no evidence of heart trouble. When he had seen this boy, there had been an acute angina, of four days' duration, and a harsh cardiac murmur had developed. Last winter one of the nurses at the hospital had been seized with a severe streptococcus angina, and had soon developed a blowing murmur at the apex. This summer he had learned from her physician that since that attack of tonsillitis she had had cardiac disease, and had lately developed evidence of lack of compensation. More recently he had had under his care a woman who had developed a faint blowing murmur at the mitral valve. It was possible that this was a hæmic murmur, but he was inclined to believe that such was not the case. From these and other cases it seemed to him most rational to look upon the tonsil as the original source of the infection.

Dr. Francis J. Quinlan said that there did not seem to him any lesions from infancy to adult life which caused so much illness as a tonsil the seat of either acute or chronic inflammation. The ring of Waldmeyer, in the vault of the pharynx, so prominent in childhood, was most favorably situated for receiving and conveying into the system all sorts of infection. Only a few months ago one of our most distinguished surgeons had fallen a victim to an infection which had started in a tonsillar inflammation.

Dr. M. C. O'Brien said that it had been often demonstrated that one small yellowish spot on the tonsil might be a prodrome of diphtheria. Many persons had been given large doses of quinine on the supposition that they were suffering from malaria, whereas even a superficial examination of the tonsil would have shown that the condition was one of an infection arising from the tonsil. We should constantly remember that the respiratory system was guarded very largely by the tonsils.

**Tonsillitis and Sudden Death.**—Dr. S. S. Jones said that he had often noted a relationship between tonsillar inflammation and rheumatism, and it certainly seemed very reasonable to look upon both as due to bacterial infection. One phase of the subject, of some importance, had not been touched upon. He had noticed a tendency in cases of tonsillitis to sudden death. These cases, he thought, might be explained by a sudden overwhelming of the heart muscle or of the pneumogastric nerve, by an infection, but it was quite possible that an endocarditis might explain some of them.

**Tuberculous Infection Seldom Starts in Tonsils.**—Dr. W. Freudenthal said that he had been especially interested in rheumatism and tuberculosis for a number of years. Some years ago he had described a series of cases in which, after an acute attack of tonsillitis, general rheumatism had followed. It seemed to him that too much stress had been laid upon the tonsils as the primary seat of the infection. The tonsils were very seldom the portals for tuberculous infection—indeed, he had never seen a tuberculous ulceration of the tonsil. When bacilli were inhaled, they could not be removed from the posterior pharynx. In the upper portion of the nasopharynx there was a quiescence, the air inhaled very seldom reaching these parts, so that the bacilli had an abundant opportunity to develop. He was convinced that the retropharynx was much more often the primary seat of tuberculous and other infections than were the tonsils. He had succeeded in proving that, in cases of tuberculosis, there were sometimes primary ulcerations of the retropharynx.

Dr. Mayer closed the discussion. Regarding the case that he had reported, he said that the diagnosis presented had not been his own, but that of the attending physician, and personally he was disposed to concur in the opinion expressed by one of the speakers, that it was a myocarditis. He would insist particularly that an ordinary tonsillotomy was not sufficient; the tonsils should be gouged out, or else removed by the method known as tonsillectomy.

**The Early Recognition of Pulmonary Tuberculosis.**—Dr. S. A. Knopf read this paper. Regarding tuberculin he said that it had proved very useful in cases of bovine tuberculosis, but it was dangerous in the human subject because of the occasional dissemination of the disease throughout the system after the use of this agent. Again, one observer in Vienna had reported the occurrence of the tuberculin reaction in twenty-seven out of one hundred cases of other diseases than tuberculosis, and Klebs, of Chicago, had claimed to have obtained this reaction in every case of chlorosis that he had subjected to this test. It was known that pulmonary tuberculosis was most frequent between the ages of seventeen and thirty-five years, and was most often observed in the poorly nourished, and those of light weight. A careful inquiry into the habits of life of the patient, past and present, and of previous illnesses, was, in his opinion, of the greatest importance as an aid to early diagnosis. Bad eaters were nearly all candidates for consumption. He believed that nearly all pleurisies were tuberculous. An increasing tendency to nasopharyngeal catarrh, especially if associated with a change of disposition or a feeling of inability to perform the usual duties, should be looked upon with suspicion. The very early occurrence of hemorrhages was not necessarily of grave prognostic significance. It should be remembered that observations made with the clinical thermometer were not useful unless made four times daily for several days in succession. A subjective symptom of some importance was a peculiar vibration of the affected lung noticed by the patient when talking loudly and energetically. The upper air passages should be minutely examined, and the nasal mucus examined for tubercle bacilli, as the finding of the latter would at least serve as one link in the chain of evidence. All that he had been able to observe concerning the pulse in the early stages of pulmonary tuberculosis was that it was persistently rapid, feeble, and more or less irregular.

**An Important Physical Sign.**—The physical examination of the chest could not be accurately made unless the patient was completely stripped to the waist. He looked upon a persistent low-pitched and rough inspiratory murmur at the apex as an exceedingly important early sign of pulmonary tuberculosis. He did not approve of administering iodide of potassium to increase the intensity of the râles heard in the chest, for the very fact that this might occur when iodide was given was evidence that there was a process of congestion which had been increased by the use of the drug, and hence such practice was obviously dangerous.

**The New Agglutination Reaction.**—Dr. Knopf said that he had made some experiments in the Health Department laboratory, with the co-operation of Dr. Biggs and Dr. Park, the serum being furnished from Dr. Lambert's service at Bellevue Hospital. The experiments with the pleuritic fluid drawn from a tuberculous guinea-pig had been a decided success. A mixture of one part serum and nine parts of the bacilli emulsion had given the true adherent film after eighteen hours, and when agitated, had broken up in the thin, large flakes characteristic of positive reaction. The experiments with the serum from a number of patients suffering from various diseases had been very much less satisfactory. Of ten cases distinctly diagnosed as pulmonary tuberculosis, four had reacted positively, two slightly, while one had given a doubtful reaction and one an absolutely negative reaction. One case of miliary tuberculosis had given only a slight reaction, and with one case, three days after a post-partum hemorrhage, a positive reaction had been obtained. A doubtful reaction had also been obtained in a case of chronic hemiplegia, and in one of alcoholic neuritis, while absolutely negative reactions had been secured in cases of tertiary syphilis and acute articular rheumatism. The diagnostic value of the method, therefore, was yet undetermined.

**Latent Tuberculosis.**—Dr. William H. Thomson said that the physician was often called upon to give an answer as to whether or not an individual had pulmonary tuberculosis. Such an answer could not be positive, and yet so much depended upon it. He knew of no other disease in which the early clinical history was apt to be so vague and unreliable. About three years ago a most interesting discussion had taken place in London on the subject of latent tuberculosis, which had been participated in by many eminent clinicians. This discussion had developed the fact that there were many cases in which the tuberculosis had been latent for five, ten, and fifteen years, and there was some reason to believe that occasionally pulmonary tuberculosis was congenital—not hereditary. All physicians must have been impressed with the great uncertainties of physical examination.

**The Emaciation Characteristics.**—In his own experience he had been especially guided and helped

by the fact that tuberculosis gives rise to a specific form of emaciation. By emaciation was meant a loss of bulk in all parts of the body except the nervous system, the most important manifestation being in the muscular tissue. *Pari passu* with the wasting of the muscles was a diminution in the bones. The leading cause of emaciation was an absorption of toxins. He was quite willing to base his diagnosis of tuberculosis on the occurrence of the specific form of emaciation regardless of the symptoms or physical signs. The chief feature of this type of emaciation was a thinning of the shafts of the long bones, so that they became flattened like laths. In other forms of emaciation the bones became more or less diminished, but were not flattened in this way. A second feature was the transformation of the muscles into ribbons. When a patient with chronic bronchitis took a long breath the hypertrophied muscles of the neck would appear prominently, while in the phthisical subject the thin, ribbon-like muscles would stand out in marked contrast with those of the bronchitis patient. Other elements easily discernible in the clinical picture of phthisis were the protruding chin, the elongated neck, and the sunken clavicles.

**Useful Early Signs.**—Dr. W. H. Katzenbach said that unfortunately cases of pulmonary tuberculosis were not usually seen by the physician until the patient had developed a cough or a hemorrhage from the lungs had occurred. The loss of body-weight was undoubtedly due, in many instances, to the absorption of toxins, and might be observable even before the body temperature had been affected. The occupation and environment of the patient should be inquired into by the physician, and the existence of the alcoholic habit searched for, as the latter had a most important bearing. The cough so commonly observed in alcoholic subjects often caused the physician to overlook the development of pulmonary tuberculosis. The changes in temperature were significant in the early stages. There might be either constant or intermittent fever; sometimes a subnormal temperature in the morning. In incipient cases the rise of temperature was often very moderate. Since influenza had become so prevalent in this locality a previous history of influenza had come to be a useful hint as to the possible nature of the malady. In cardiac disease hæmoptysis was not very common, and hence this cause of hemorrhage should be excluded before deciding that the hemorrhage was the result of a tuberculous process in the lung. Quite recently he had seen an example of pulmonary tuberculosis associated with cardiac disease, thus making this differentiation of the source of the hemorrhage peculiarly difficult. The cases exhibiting, on inspection, the features described by the last speaker were usually those which had already reached an advanced stage, and naturally in such the diagnosis was not so difficult as in the earlier stages. He had found it a useful procedure to stand behind the patient, and place the thumb on the scapula and the finger under the clavicle, and while making firm pressure ask the patient to take a deep breath. The occurrence of pain on one side under these conditions often pointed to involvement of that lung. Another useful sign was the conduction of the heart sounds at the apex of the lung and under the clavicle.

**Tuberculin and Serum Tests Unreliable.**—Dr. Alexander Lambert said that he was somewhat more favorably disposed toward tuberculin than was the reader of the paper. He had been struck by the fact that an exceedingly slight tuberculous lesion—even a healed lesion—would give a marked reaction. From this it was evident that the tuberculin reaction gave no hint as to the extent or severity of the tuberculous process. In pure tuberculosis an early sign, frequently obtainable, was the existence of a subnormal temperature in the morning, or a subfebrile temperature in the evening. A case was cited in which an individual who he had had no reason to suppose was tuberculous, had complained of a peculiar vibration in the chest whenever he hummed a tune. A physical examination of the chest had then revealed a lesion there. At the time he had not given this sign any particular thought, but had been reminded of it this evening by a reference to this sign in the paper just read. He had watched the experiments made at the health department laboratory with the serum, and had been profoundly impressed with its utter unreliability, other signs and symptoms being, in his opinion, far more valuable.

**Spontaneous Arrest of Tuberculosis Common.**—Dr. Herman M. Biggs said that no one could do much pathological work without becoming impressed with the fact that a large number of cases of tuberculosis passed unrecognized. The difficulty in recognizing this disease seemed to him to be due not so much to a dearth of diagnostic methods, but a failure to use them systematically. In a large series of autopsies on adults dying in the charity hospitals of this city he had found that in about sixty per cent. of the cases tuberculous lesions were present, yet in hardly one-half of these had the existence of this disease been suspected. The fact, that in such a large proportion of cases occurring among the poor, and under the most unfavorable surroundings, the process had been naturally arrested, was certainly food for deep thought. As a rule, the extent of the lesion in cases of tuberculosis was considerably greater than supposed during life.

**Koch's Use of Tuberculin.**—He had used tuberculin quite extensively, and not always with complete satisfaction; nevertheless he believed it was of very great service in those cases in which we could not arrive at a definite conclusion; and yet it was important that such a conclusion should be reached. He had been told by Koch about four years ago that tuberculin was administered to every person in the Berlin Pathological Institute in whom there was not distinct evidence of the disease. It had been administered under such conditions to over five thousand persons. The practice had been to begin always with a small dose—1 mgm.—and if there was no reaction at the end of four or five days, to give 2 mgm., and at the end of four or five days more, 5 mgm., and if on the repetition of this dose after another interval of four or five days there was still no reaction it was considered reasonably certain that no tuberculosis was present. Dr. Biggs said that this method of diagnosis had cleared up the doubt in his mind in a number of instances in which he had found it impossible to come to a definite conclusion by other means.

**Sputum Examinations Often Unsatisfactory.**—Dr. John Blake White commented upon the fact that the reader of the paper had laid greater stress upon the diagnostic value of the symptoms and physical signs than on the examinations for the specific bacilli, and added that this had been his own experience. He was glad to hear the condemnation of the tuberculin test, for he had no faith in it whatever, and was positive that similar results could be obtained by the mere injection of chemicals into the circulation. This opinion was founded on experiments made by himself some years ago at the City Hospital. He agreed with Dr. Thomson regarding the special kind of emaciation present in pulmonary tuberculosis.

Dr. Knopf closed the discussion. He said that while he had been greatly interested in the clearly drawn picture of the emaciation which characterizes tuberculosis, he could not but feel that this sign was present only in the later stages.

## THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Stated Meeting, November 27, 1899.*

GEORGE B. FOWLER, M.D., PRESIDENT.

**Cancer of the Uterus, and Its Early Diagnosis.**—DR. THOMAS S. CULLEN, of the Johns Hopkins University, presented a paper on this subject. He said that there were three different kinds of mucous membrane in the uterus, viz.: (1) that of the vaginal portion; (2) that of the cervix; (3) that of the body; and hence there were three definite varieties of carcinoma, and only three, in the uterus. His object in coming here at this time was to try and impress upon those present that there was no difficulty in making a diagnosis of carcinoma of the various portions by an examination of the scrapings. A number of excellent plates were exhibited in order to give a proper conception of the histology of the normal uterus. The presence of glands at a considerable distance from the mucosa was not, as had been supposed by some, an indication of malignancy. An idea that had gained quite general acceptance was that the mucous membrane of the uterus was shed at each menstrual period, but some recent studies had shown that such was not the case. Plates were exhibited showing one very characteristic appearance of carcinoma of the cervix, viz., myriads of minute finger-like processes. One of the plates presented demonstrated conclusively that the glands in the body of the uterus took no part whatever in squamous carcinoma of the cervix. Rarely in cancer of the cervix was there an extension to the lymphatic glands. The cells in cancer of the cervix were usually rather large, and the lymph radicles rather small. In the breast, on the other hand, there were small epithelial cells and large lymph channels. It was probable that the growth must extend far out into the broad ligament before extension into the lymphatic glands could take place. In one case, in which there was a squamous carcinoma of the cervix associated with pregnancy, the woman had been kept under observation until term, and then both uterus and child were removed. The child had lived four or five months, and had then succumbed to some intercurrent trouble. The mother was still alive and well, though the operation had been done two years ago. A very curious and interesting feature of the case had been the presence of a normal decidua formed on the lip of the external os, as well as in the uterus. In one case, in which a diagnosis of malignancy had been made from an examination of the scrapings, after removal of the uterus it had been impossible even for an expert to distinguish, from the external appearance, between this and the normal uterus. However, on cutting open the uterus, a malignant growth had been found. In such a case diagnosis without microscopical examination would have been impossible. The glandular growth of the cervix, the speaker said, was the most malignant type of carcinoma found in the uterus. True erosion of the cervix was characterized by loss of substance and disappearance of the epithelium, but a large number of so-called erosions were nothing more than eversions of the normal mucous membrane. As the blood-vessels in this portion of the mucous membrane were covered only with a layer of epithelium the surface appeared red. When such a surface was treated, as in the old days, by repeated applications of iodine, the result was a thickening of the epithelial covering and an appearance resembling healing of the surface, so that it looked like the outer portion of the cervix. This had led the physician to suppose that the "erosion" had been healed; but in a few weeks the thickened epithelium would be exfoliated, the blood-vessels would once more show through the thin epithelium, and the physician was then led to believe that the "erosion" had returned. Occasionally the hardening and dilating of the glands of the cervix would give an appearance suspiciously like carcinoma. In cases of adeno-carcinoma of the body of the uterus it was impossible to say definitely, by palpation, that malignant disease was present; indeed, such might be the case and still the uterus be diminished, rather than increased in size. In this class of cases one must depend upon microscopical examination for a diagnosis. In all cases in which the patient was between thirty and sixty years of age, and there were hemorrhages, and the diagnosis was not clear, the uterus should be curetted or a portion of the cervix removed. The diagnosis of malignancy having been made, no time should be lost in removing the entire uterus. It should not be forgotten that in securing the scrapings the curette must be systematically applied to the whole interior of the organ, otherwise the diseased portion might be passed by.

DR. PAUL F. MUNDÉ said that the great difficulty in the past had been to induce the patient to come to the physician sufficiently early to allow of scrapings being taken for diagnostic purposes. Five years ago he had stated, in a clinical lecture, that he had had five cases presenting irregular hemorrhages, in which, by microscopical examination of scrapings from the uterus, the late Dr. Heitzmann had made a diagnosis of lympho-sarcoma or of adeno-carcinoma, and had advised immediate removal of the uterus. Notwithstanding the high authority who had made this diagnosis, these cases had been treated by the application of acids and curetting, and all of the patients were to-day alive and well. He had felt that friability and readiness of certain so-called granulation tissue to bleed was a decided indication of malignancy, and that when these signs were not present, in spite of the microscopical findings, it was probable that there was no malignant disease present, or, at any rate, that the latter was in its incipiency. Unless we were willing to advertise in the daily newspapers, as the cancer-cure quacks were in the habit of doing, he did not see how we were to get these patients early enough for such methods of diagnosis. He had found on his case-book, covering the period of the last ten years, one hundred and thirty-two cases of malignant disease of the uterus, in one hundred and twenty-nine of which it had been situated in the cervix. Of these one hundred and twenty-nine cases of carcinoma of the cervix, in only four had the patient been seen sufficiently early to expect a cure. Of these one hundred and twenty-nine cases, vaginal hysterectomy had been performed nineteen times. He had given up vaginal hysterectomy except for carcinoma of the body of the uterus. For carcinoma of the cervix he did not consider vaginal hysterectomy a very good operation. In one instance he had tried the thermo-cautery, and had at first congratulated himself on the thorough removal of the carcinoma, but within a short time the patient had had three severe hemorrhages, and then, on performing abdominal section, he had found that the slough left by the cautery had involved the upper branches of the uterine artery. The patient had been so prostrated by these hemorrhages that she had not survived the shock of the abdominal section. Regarding erosions, he said that many years ago he had expressed the opinion that many of these erosions, occurring independently of cervical laceration, might be best relieved by excision of the red papillomatous mass, and suture of the cut surfaces. One year ago he had published a separate article on this same subject, and had described the good results of such treatment.

DR. W. GILL WYLIE said that he did not doubt that correct diagnosis of malignant disease of the uterus

could be made by such expert microscopists as Dr. W. H. Welch, but he had long been of the opinion that but few were competent to do this work satisfactorily. Again, the practice of excising a piece of tissue for examination was fraught with much danger, because such interference seemed to invite a rapid extension of the disease and greatly diminished the chances of success from any subsequent operation. The older the patient the slower the progress of the disease, and the longer the interval before recurrence. He had lately seen a carcinoma occurring in a woman only twenty years of age. He firmly believed that cancer was a local disease, and that carcinoma of the uterus could be cured—indeed, that hundreds, if not thousands of cases could be cited in proof of this statement. The great secret of success was not to disturb the cancer until ready to remove thoroughly all of the disease. Hysterectomy for carcinoma could be done with almost no risk.

Dr. Henry C. Coe said that it was impossible to add anything to the beautiful pathological presentation of the evening, but the paper had emphasized the fact that it was the duty of the physician, whenever there was a suspicion of malignancy, at once to explore the interior of the uterus, and, if it seemed necessary, to excise a portion for microscopical examination. It was strange that so many incurable cases of carcinoma of the uterus were still met with, and the explanation seemed to be that they were treated palliatively for a long time. It was not uncommon to meet cases of obstinate hyperplasia in which the pathologist reported a negative result upon his examination. This brought up the interesting question as to whether such an endometritis was a preliminary stage of carcinoma, and whether radical operation was justifiable under these circumstances. Again, in cases of small nodules of adeno-carcinoma the prognosis was stated to be good, yet he had had two or three such in which there had been a comparatively rapid recurrence. He would not be so hopeless as Dr. Mundé, yet he had seen too many cases of recurrence, after four or five years, to feel as Dr. Wylie did. He had seen too many recurrences after a long time to feel like speaking of a cure in a case of carcinoma until a period of five or ten years had elapsed. He heartily agreed with Dr. Mundé that, by excising an erosion of the cervix, one often anticipated the development of carcinoma.

Dr. Cullen closed the discussion. He said that the only symptom of carcinoma, in the early stages, was hemorrhage, and that was certainly not a reliable one; hence, the necessity for relying upon the microscope. Regarding the pathological work at the Johns Hopkins Hospital, he would say that in every instance, since 1893, the diagnosis made by microscopical examination of the scrapings had been confirmed by the subsequent examination of the uterus, and both the scrapings and the substance removed by operation had been preserved, and could be inspected at any time, so that this statement admitted of easy verification. In that institution, there had been one hundred and twenty or one hundred and thirty cases of squamous and adeno-carcinoma of the cervix, and nearly fifty cases of carcinoma of the body. In quite a large number of those presented here to-night by plates, the patients had been known to be alive six or seven years after operation. In a not inconsiderable number of cases the microscopist was apt to be misled by a gland hypertrophy, occurring perhaps in connection with a concealed pregnancy, in which the appearance closely simulated that presented by carcinoma. The youngest case on record—one carefully preserved at Prague—was an adeno-carcinoma of the cervix occurring in a girl aged eight years. In all cases of myoma, associated with hemorrhage, there was always a possibility of the coexistence of carcinoma.

## OUR LONDON LETTER.

(From our Special Correspondent.)

MEETING AT COLLEGE OF SURGEONS—MEDICAL SOCIETY; CASES EXHIBITED—CLINICAL SOCIETY; INTUSSUSCEPTION OF MECKEL'S DIVERTICULUM, RUPTURED KIDNEY, SPLENIC ANÆMIA—PATHOLOGICAL SOCIETY; THE KLEBS-LOEFFLER BACILLUS IN "PIGEON CANKER"—DEATH OF DR. REGINALD SOUTHEY.

London, November 17, 1899.

Yesterday the annual meeting of the fellows and members of the Royal College of Surgeons was held, Mr. Howse, V.P., in the chair. The report I noticed last week. A resolution of regret that the council disregarded the resolution of last July, and affirming that the new charter would afford an opportune occasion to give the members their rights, was carried by forty-two votes to six. In the talk on the matter Sir T. Smith said the fellows had been consulted on two occasions and voted against the proposal. On the other hand, it was suggested that the fellows had not been asked to give a plain yes or no. The chairman repudiated the notion that the council had suggested the replies by the form of the question. Further resolutions were carried against serving on medical aid associations and against sham diplomas like those of the Obstetrical Society. Another recommended notice of meetings in future to be posted to fellows and members.

The attendance of fifty persons at a meeting of this kind is not very encouraging to the reformers, and the Council will no doubt go on their way unabashed. The fellows, too, seem to have no shame at their position and will be brought to yield justice only by drastic measures. Meantime members are expected to be satisfied by the permission of the Council to wear a gown—a permission the Council has no authority to give or withhold.

The Medical Society had a clinical evening on Monday, when some interesting cases were shown. One was of a man of seventy-one years who was brought forward as recovering from aphasia and agraphia, supposed to be due to slight hemorrhage at the centres concerned. Another was a boy with a systolic thrill over the base of the heart, audible also in the back and neck, with hypertrophy of the left ventricle, which was thought by some to be due to congenital defect of the aortic valves, while others conjectured persistent ductus arteriosus in spite of there being no cyanosis. A man aged twenty years had a large hernia cerebri, which had followed an operation undertaken on account of symptoms of a tumor which had lasted some four years. Much relief was reported, although no tumor could be reached. Another obscure case was an Italian, with loss of flesh, weakness, vomiting, and pigmentation of the skin and nails, but this last was of long duration and conjectured to have been caused by his occupation—asphalt-laying. There was no history of malaria, but both liver and spleen were enlarged. Increase of white corpuscles and eosinophiles with decrease of red corpuscles was reported. A case of lockjaw relieved by deep incision of an inflamed gum elicited mention of two somewhat similar cases.

At the Clinical Society, Mr. Bertram Robinson read an account of a case of acute intestinal obstruction due to an intussusception of Meckel's diverticulum in a boy aged five years. The symptoms were very obscure, but under anæsthesia a lump was felt in Douglas' pouch about three inches long, firm and tubular. This did not clear up the case, and a mid-line incision was made. The reduction of the inverted diverticulum was

impossible, and it was excised. The child died two hours afterward, though he revived at first. Mr. Symons mentioned that he had seen cases of obstruction from the diverticulum, but not of intussusception following.

Mr. Bland Sutton related a case of primary nephrectomy for rupture of the kidney caused by a cab running over the patient, a man aged thirty-five years. There were marked signs of internal hemorrhage and large swelling in the right loin, but no contusion or scratch on skin. Blood appeared in the urine. Mr. Sutton made an incision in the right linea semilunaris and found the other viscera uninjured; he then detached the peritoneum overlying the swelling in the loin, and found the kidney torn right across, so he removed the fragments and surrounding clot. The patient made a rapid recovery. Mr. Sutton would use the term primary in cases in which the kidney is removed within twenty-four hours after an injury; when days or weeks had elapsed, he would say secondary nephrectomy. In reply to inquiries why he did not close the abdominal wound on finding a ruptured kidney, and remove it from behind, Mr. Sutton acknowledged his course to be debatable. He had been brought up as a "loin surgeon," but had gradually come round to Mr. Knowsley Thornton's plan. He had now dealt with twenty-five cases in this way, and found the peritoneum could, with a little care, be brought together so as to shut off the general peritoneal cavity, and this plan gave a better means of draining than from the loin.

Mr. G. R. Turner related a similar case in which he had operated through an abdominal incision. He had been led to do so from seeing a case in which both liver and kidney were injured.

Dr. Norman Dalton related a case of enlarged spleen in a woman, aged thirty-eight years, who died suddenly. There was great anæmia, but no hemorrhages. At the post-mortem the stomach was found strangulated, and there was a perforation at the cardia from sloughing. The transverse colon lay above the stomach and before reaching the left lumbar region encircled the junction with the œsophagus. This abnormality was considered congenital. The grip of the colon alone would not cause obstruction, but when the spleen became so large, its weight on the gastro-splenic ligament pressed the cardia against the encircling colon, as shown at the post-mortem by traction on the ligament. Finally extra distention twisted the cardia and pylorus and produced strangulation. The splenic vein may have been compressed from the first, and to that cause Dr. Dalton was inclined to attribute the enlargement of the spleen, while the anæmia and accompanying fever might be due to the condition of the stomach, for other splenic affections were excluded. He admitted that the case resembled those called splenic anæmia or splenomegaly, but he was not satisfied that these constituted a pathological entity, as they could generally be explained without calling a new disease into existence.

Can you suggest a suitable punishment for grown-up men who compound such words as splenomegaly? They seem to have escaped the discipline of the last generation of school-masters. This particular word, whether originated by Banti or some one else, is perhaps no worse than many which have been introduced in spite of protests. But it is time medical writers ceased to provoke the taunt that they use a jargon as vile as Volapük.

The new departure made by the Pathological Society seems to be a success. The first of the laboratory meetings was held on the 7th inst. at the Jenner Institute. There, as elsewhere, bacteriology was in the ascendant. So much is this the case that it looks as if we should have to hand over this branch of study to experts and give up the attempt to keep pace with their advances. The communication at this meeting which will perhaps excite the most interest among practitioners was made by Drs. MacFadyen and Hewlett. They have found an organism in pigeons which closely resembles the Klebs-Loeffler bacillus in its morphological, cultural, and staining peculiarities—in everything, in short, save in its pathogenic and toxic properties. The story of this find is amusing. They received a swab in the usual way and reported that the diphtheria bacillus was present. Then the sender told them it had been taken from the throat of a pigeon suffering from "canker." This disease is common in these birds, both on the scalp and in the throat. It looks like a warty growth and is quite a local disease. On this information they procured a number of diseased pigeons and found the bacillus in all. The next step was naturally to examine healthy pigeons. This was done, and again the bacillus was found in the throat of every bird. There are two strains of the organism with very slight differences. The one most like the Klebs-Loeffler was the one found in the healthy birds. Further investigation is promised. If the organism should be found in all healthy pigeons, it is so widely diffused as to deserve the most earnest attention of experts. If it can be distinguished only by not producing diphtheria, there seems a need for further study of the etiology and pathology of that disease.

The other communications at the meeting were, as I have said, chiefly bacteriological, and included one by Dr. Klein on "The Bacillus of Pseudo-Tuberculosis," one by Dr. Dean on "Diphtheria Immunity," and others by Drs. Salter, Eyre, Washbourn, and Shattock, relating to tetanus toxin, antipneumococcic serum, and chromocyte clumping, illustrated by lantern slides, etc.

The death is announced of Dr. Reginald Southey, formerly physician to St. Bartholomew's Hospital and afterward a commissioner in lunacy. Dr. Southey took his M.D. at Oxford in 1866, and the same year was elected F.R.C.P. The next year he delivered the Gulstonian lectures and in 1881 the Lumleian lectures. He contributed to St. Bartholomew's Hospital reports on "The Normal and Pathological Anatomy of the Kidney," and translated the article on diseases of that organ in "Ziemssen's Cyclopædia." Never very strong, his health had failed lately, and he died on the 8th inst., aged sixty-four years.

## STATE SANATORIA FOR CONSUMPTIVES.

To the Editor of the Medical Record.

Sir: The energy and enthusiasm of certain physicians in behalf of a State sanatorium for the treatment of incipient tuberculosis are very remarkable in view of the fact that competent authorities assert that a majority of the incipient cases recover when properly treated at home. What is needed is not a State sanatorium for the treatment of this class of cases, but an early diagnosis and the institution of proper hygienic and dietetic treatment combined with such therapeutic measures as promote the general health. Susceptibility to tuberculous infection is largely due to a depreciated vitality caused by improper habits of living.

The power of the State should therefore be invoked in the direction of removing the primary causes of a depreciated vitality, but it should not be used to aid in treating a symptom.

The curriculum of our public schools should be revised; much which it now contains should be expunged, and a comprehensive-graded course in physiology, hygiene, and dietetics added in which each child should be thoroughly drilled. When knowledge of this kind becomes widely diffused, the first great step

toward eradicating tuberculosis will have been taken.

There is, however, a class of cases which require isolation, as a prophylactic measure, viz., those which have advanced beyond the possibility of a cure. These are the cases which no institution cares to receive: they become centres of infection and should properly receive the attention of the State.

But to saddle upon the taxpayers the expense of caring for incipient cases which do well when properly treated at home, while the causes which operate to render the individual liable to contract the disease are ignored, is a proposition which should be promptly voted down by the profession, by the taxpayers, and by our legislators.

JOSHUA L. BARTON, M.D.

57 EAST FIFTY-FIFTH STREET, NEW YORK,
November 25, 1899.

## DR. GEORGE M. EDEBOHLS AND THE NOMENCLATURE OF APPENDICITIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your issue for November 25, 1899, Dr. Edebohls gives a review of the history and literature of appendicitis. In the paragraph "Nomenclature," he omits the term "perityphlitis," a term which is just as firmly established by long and universal usage in some countries as the word appendicitis in America. I do not wish to defend the one or condemn the other, but simply to establish a fact. I have been told that Dr. Morris was not the nomenclator of ecphyaditis, and I know positively that Dr. Gerster was not the first who named the disease scolecoiditis. Dr. Edebohls in saying, "We bow to the inevitable . . . and accept the term appendicitis," speaks in the pluralis majestaticus, because Dr. Edebohls is not the medical profession.

Our esteemed colleague, who has presented to us such an exhaustive bibliography, and has mentioned two supposed nomenclators, has omitted to inform us of the name of the man who invented the term appendicitis. Since "we" are so proud of this word, let us know the benefactor of mankind who has given it.

A. ROSE, M.D.

## VACCINATION VS. SEPSIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Your recent issue contained a reference to the death of John Burns, of Geneva, N. Y., alleged to have died from the effect of vaccination. The facts of this case place those persons entirely in the wrong who have taken pains to give such widespread notoriety to the case in the newspapers, heralding it as another death from vaccination, and advising all right-minded persons to rise up against the barbarous practice. I take pleasure, therefore, in placing the matter in its true light.

The vaccination was performed by Dr. G. S. Means, of Bellona, with one of Mulford's points, which was scarcely a month old. The arm and instruments were made sterile, and after the operation a bandage was applied, the parents being directed to renew it with a clean one after the seventh day. Nine days after vaccination the boy was taken to Geneva, to church, on a cold, stormy day, and after that he was sick enough to be kept in bed; but the room was cold and damp, and he did not have sufficient clothing.

Nineteen days after vaccination the doctor was called to see him, and found the arm and corresponding side of the face inflamed, tense, and œdematous, with lymphatic involvement. The temperature was 102.5° F., pulse 100. The pock was covered with seven layers of cloth saturated with pus and foul-smelling. Inquiry revealed that the first cloth had been applied a week after vaccination and the others in successive layers as the under ones became saturated.

Upon removal of these cloths an ulcer was found containing half an ounce of foul pus; its edges were infiltrated, and it was lined with dead tissue. A condition of general septicæmia was recognized, with local involvement of the left arm and left side of the face and neck. Prompt and energetic measures were employed for the boy's relief, but he died the following day.

This is another of those cases in which culpable neglect of a small wound leads to serious results, and might have occurred had the wound been from the prick of a pin. The vaccination was performed skilfully with good lymph, but through disobedience of instructions the simple aseptic wound was changed into a foul septic sore, containing dammed-up secretions that were readily absorbed with fatal results.

EDWIN R. BISHOP,
*Health Officer, City of Geneva.*

## OPIUM TREATMENT IN APPENDICITIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Dr. Rupp's defence of medical treatment in appendicitis, in the MEDICAL RECORD for November 25, 1899, is more hopeful in its tone than the response of some of my opponents, because he has been able to lay aside the matter of personal feeling, and to confine himself to the subject. His letter may well stand as an expression of opinion from a representative practitioner, and as such it illustrates the difference between medical and surgical standpoints, and the reason why surgery is a science and medicine an art to-day. The surgeon's practice in appendicitis is based upon accurate data; the physician's practice in these cases is based upon speculation as to the condition of any given appendix. Dr. Rupp says: "Some cases are so mild that they get better with bed-rest and dieting, others demand opium, and still others cannot get well unless the surgeon's knife and technique help them to do so." Granted! Dr. Rupp is now to tell us which case is to run which course, or he is to admit that the nature of each case is determined afterward.

I have recently lost two personal friends from appendicitis right here in New York, their deaths only forty-eight hours apart, and they died because their cases were believed to have been of the mild sort. If Dr. Rupp will step into the library and take down the last edition of "Lectures on Appendicitis," he will find the testimony of a series of consecutive unselected appendicitis patients who state that they had less suffering under surgical treatment than under any form of medical treatment. They speak from a personal experience with almost every phase of the disease, and with many sorts of medical treatment. There will be found also the reasons for the estimate that the deaths from appendicitis in the practice of physicians in the United States is more than fifty thousand annually. The physician's prognosis in cases of appendicitis is speculative, and the surgeon's prognosis may be made very accurately. Dr. Rupp says that "cases differ, and consequently they demand different methods or plans of treatment." My argument is that appendicitis cases are due to bacterial infection of the appendix, and are consequently alike. We are not speaking of cases of suspected appendicitis. I do not believe in operation in such cases. One physician has sent me four cases for operation for appendicitis, and not one of them was operated upon. In the

last case the patient, family, and physician were all incensed because of my refusal to operate, but none of these patients had infection of the appendix. I have examined three physicians in one morning, all of whom thought that they had appendicitis, but not one of them had an infected appendix. Dr. Rupp says that "when the general practitioner tries to defend his practice, he has one great disadvantage to contend against, and that is his inability to produce a great array of statistics." Why this inability? It is simply because there has not been enough scientific spirit and enough public spirit in any one to produce the statistics that we all want on medical treatment in appendicitis. I have been trying for years to persuade physicians to give us the histories of cases under observation for the definite period of two years, with a report on the number of deaths, the number of recurrences, the length of time wasted in bed, the condition of the patient's general health, and the condition of the appendix as determined by skilled palpation. Any one who can acquire the skill to palpate ovaries and oviducts can just as readily palpate the appendix. No statistics for the two-year period have been forthcoming, and the opportunity for some one to distinguish himself and to render a public service at the same time is at hand.

Argument is made that the physician does not like to frighten his patients by calling in the surgeon, and he does not like to ask the patient to pay a large fee in a case in which it may not be necessary. Why not tell the patient the difference between medical and surgical statistics that are available, and let the patient get frightened in his own way? As to the fee, it is true that we sometimes like to charge several thousand dollars for an operation that makes the death rate, the suffering rate, and the loss-of-time rate less than it would be under medical treatment, but there are a great many patients who prefer to make their own choice in this matter when they really understand about it, and there is perhaps no patient so poor that he must go uncared for. So far as I am aware, no physician has as yet been able to defend medical treatment of any sort in appendicitis when proper treatment is available.

If medical treatment is one's choice of procedure, then he is subjecting his patients to a practice which he is unable to defend. A lawyer said to me recently: "It is astonishing the way you physicians differ upon questions involving acutely the matter of life or death for an appendicitis patient." I said to him: "We do not need to differ. Our knowledge upon the subject is thoroughly classified and available for any one who has the time to master the subject."

ROBERT T. MORRIS, M.D.

49 WEST THIRTY-NINTH STREET, NEW YORK,
November 28, 1899.

---

**Microbes in the Beard.**—Dr. Schoull, of Tunis, has discovered that the beard is simply a "happy hunting-ground" of bacilli. He has proved it upon the guinea-pig whom he has inoculated with the "material obtained from beards and mustaches," with results distressing to the guinea-pig, and alarming to those who had been in more or less contact with the beards and mustaches aforesaid. This is a very disagreeable discovery, and may seriously affect the popularity of a form of facial adornment which has hitherto been regarded as open to no other objection than that it is a nuisance to its wearer when in the act of taking soup. But what are a few shreds of vermicelli compared with a whole army of able-bodied bacilli lying in ambush for their victims, and, what is more, ready to make victims of anybody who happens to come within their range?—*Sanitarian.*

## Medical Items.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 2, 1899:

| | Cases. | Deaths. |
|---|---|---|
| Tuberculosis | 199 | 134 |
| Typhoid fever | 53 | 19 |
| Scarlet fever | 149 | 7 |
| Smallpox | 2 | 0 |
| Measles | 275 | 11 |
| Diphtheria | 200 | 41 |
| Laryngeal diphtheria (croup) | 7 | 13 |
| Cerebro-spinal meningitis | 0 | 3 |
| Chicken-pox | 21 | 0 |

**Skulls and Brain Capacity.**—Professor Arthur Thompson, in the October number of *Knowledge*, deals with the form of skulls and brain capacity. The average weight of a man's brain is about fifty ounces, that of a woman about forty-five ounces. This difference between the sexes is less marked in savage than in civilized races, and is apparently explained by the fact that in the higher races more attention is paid to the education of the male than the female, and consequently the brain is stimulated to increased growth.

**Character Shown in Hats.**—Show me how a man wears his hat, and I will tell you what manner of man he is. Notice yourself how he wears his head-gear, and you can make a fair estimate of his character. Select the man whose hat seems to have been made for him, and which he has set squarely upon his head as if it were designed so to do, with never a tilt to the left or right, fore or aft. He is a methodical and a comfortable man with a rare endowment of common sense. He is not given to flights of fancy. He obeys the injunction of the homely philosopher, who advised all mankind to keep its feet on the ground. Men whose hats are always too large for them are of reflective habits. They are careless of externals, and given to introspection. They are philosophical and likely to fall into fits of preoccupation. They are apt to ignore mere details. Conspicuously of this class was Mr. Gladstone, whose hat brims always showed a disposition to reach his ears. Men whose hats are always too small are vain and finical. The man who wears his hat drawn over his eyes may not be a "crook," but he is undoubtedly a "schemer." He excels in strategy, whether he uses his gifts in an army campaign or in a coup on Wall Street. He is not cheerful, in fact is given to gloomy meditation. Much more does the man who habitually wears his hat pushed off his forehead enjoy the confidence of his fellow-men. The man who wears his hat off his forehead is essentially frank. He is admired by those who do not agree with any of his views, for his straightforwardness; if nature has not gifted him with a singing voice, he whistles. The man who places his hat on one side is independent, self-assertive: he is in danger of becoming vicious. He is a "sport" by nature if not by practice.—*Hatter's Gazette.*

**How to Cure Worry.**—Many persons would be only too glad to hear of a cure for worry. The *Piccadilly Magazine* has a contributor who professes to have solved the problem, and gives the remedy, which is as follows: "The psychological basis is what is known as the law of attention, the physiological basis is in the undoubted control of the body by the mind through the nervous system. This is the formula: When the

symptoms of worry begin to manifest themselves, when your mind gets to dwelling upon some one troubling matter with feverish insistence, when you find yourself depressed or irritable or overstrung, or full of foreboding, then go into your room and lock the door. For the first application of this prescription you must be absolutely alone and in silence. After a while you may be able to make these conditions for yourself anywhere, by the complete withdrawal of your mind even in the midst of a crowd; but at first you must be quite alone. Loosen your garments completely; lie down in the most restful position you can assume; avoid raising the head too high, thus cramping the neck and impeding circulation. Now close your eyes for a few minutes, and raising the arms let them fall and lie loosely and naturally above your head. Lie thus for a minute or two, and then begin to take deep, long breaths, as deeply as possible, exhaling quietly and naturally. Keep this up for five minutes, until you are sensible of a real relaxation and refreshment of the body. You will then be in the physical condition to take up the mental work which you need to do."

**The Russian Red Cross Society.**—The Russian Red Cross Society is one of the best organized of any of the societies devoted to the tending of the sick and wounded in time of war. Not only is it active at home, where during the past summer it has been busily occupied in relieving the famine-stricken peasants of east European Russia, but also in foreign countries in which Russian interests and sympathies are concerned. Its doctors and nurses gained a great and well-deserved reputation in Abyssinia at the time of the Italian campaign against the Negus, and also during the Greco-Turkish war. At the present time, in addition to the decision arrived at to dispatch a strong medical detachment to aid the Boers, a sanitary corps with doctors and Sisters of Mercy will be sent to Manchuria to fight the plague, which has broken out among the Chinese laborers on the Manchurian railway. In the Transvaal it is stated that it will offer help to both belligerents, although the Russian *Herold* somewhat qualifies this statement by adding: "We preserve appearances by this dual proposal, but we do not conceal our views."

**The Modern British Recruit.**—Recently at the United Service Institution, Lieutenant-Colonel C. M. Douglas, V.C., M.D., read a paper on "The Recruit from a Depot Medical Officer's Point of View," and said that "a comparatively small collection of highly trained soldiers formed the nucleus of the British army, round which were aggregated a heterogeneous mixture constituting the 'auxiliary forces.'" Speaking of the recruits who enlisted in the north of England and in Scotland, he said the great majority were sallow, downcast, nondescript youths, mostly artisans. Candidates were carefully examined in respect of weight, height, circumference of chest, lungs and heart, head, and teeth. A really good set of teeth was rare except among agricultural recruits. The minimum physical standard was low: weight, 115 pounds; height, 5 feet 3½ inches; minimum girth of chest, 33 inches; age, eighteen years. This was not a high type of British male. But the short, muscular, well-formed man often made a good soldier, and was more active than the big man. Professor Dudley Sargent, of Harvard University, took the measurements of several thousands of American students aged from sixteen to twenty-six years. This was the average result: age, 22¼ years; weight, 156 pounds; height, 5 feet 8½ inches; girth of chest, 34½ inches minimum, 36½ inches maximum; right upper arm, 11½ inches; right forearm, 10¼ inches. Of the British recruit the results were, on the average: age, 19⅛ years; height, 5 feet 5⅝ inches; weight, 126 pounds, girth of chest, 33½ inches minimum, 35 inches maximum; right upper arm, 10½ inches; right forearm, 9½ inches. The usual average of rejections was a little over a third, but sometimes they amounted to two-thirds, and in one case the army medical officer declined the whole batch of twenty-five or thirty. It was said the continental recruit was worse than the British, but the comparison was not fair. Compulsory service was a net enclosing all the fishes, big and little; in the British net the meshes were made as large as we dared in order to capture only the best fish and let the others go. Want and hunger were unfortunately the invisible recruiting sergeants of the British army, and the men were too often black sheep. But the effects of drill and discipline on the degenerates in the ranks was amazing, and on the whole the raw material of the British army was not quite so bad as many pessimists would have us believe. Unfortunately soldiering was a trade looked down upon in the working class, who disliked discipline and longed for better pay and shorter hours. The army of the past had in it many blackguards but fewer degenerates; the species was almost unknown then among the ranks. The inference was that there was more of the fighting spirit in the blackguards than in the degenerates, and it was the fighting spirit that was essential.

**Fund for Soldiers' Widows and Wounded Soldiers in Great Britain.**—The revenue account and balance sheet of the imperial war fund for December 1, 1898, which, says the London *Times*, has just been issued, shows that since the institution of the fund in 1882 a total of about £8,000 ($40,000) has been distributed up to date, and that there is still close upon £5,000 ($25,000) in hand. The battles of Atbara and Omdurman, and the Cretan troubles, however, caused claims which had not been discharged at the time the report was prepared. The fund is immediately available for the assistance of any widow of a soldier killed in action or dying of wounds or disease on active service. Owing to the war in South Africa the calls made upon this fund will be infinitely greater than at any time since its inception, but it is satisfactory to note that, doubtless to a certain extent by Rudyard Kipling's stirring poem, the purse-strings of the Britisher of every station have been widely opened, and there is no reason to fear that those near and dear to him, whom the soldier has been obliged to leave behind, will suffer the stings of poverty. Among the largest subscribers is Mr. William Waldorf Astor, who donated $25,000.

**Do Medical Men Receive Commissions?**—Ex-Justice Fry, when he accused the medical profession of Great Britain of receiving secret commissions, raised a hornet's nest about his ears. The correspondence in the English journals regarding the matter has been both voluminous and acrimonious, and left-handed compliments have been bandied on all sides. The verdict, though not entirely definite, was at any rate negative, and the case for Mr. Justice Fry may be regarded as not proven. Probably there have been instances in England in which medical practitioners have received commissions from druggists, but Mr. Fry's sweeping assertion that all the principal doctors in London were venial in this respect has been successfully rebutted. "It is said," says *Science*, "that in the United States physicians do not receive commissions from pharmacists to any considerable extent, but suit has just been brought by a San Francisco physician for $300, which he claimed as a commission on prescriptions sent to a druggist. Complaint is also made that some of the younger surgeons in New York ophthalmic hospitals receive commissions from opticians." We believe, however, that this charge has

been made only on hearsay and has not been substantiated; therefore until it is clearly shown to be the case it is only fair to give the accused the benefit of the doubt.

**Russian Institute for the Study of Malaria.**—An institute for the study of malaria has been established at Kiew as a department of the St. Petersburg Institute of experimental medicine.

**Kissing the Book** is held by English jurists not to be compulsory, and still a coroner has recently refused the request of a witness to be relieved on sanitary grounds. There has been some talk of celluloid-covered Bibles and antiseptic sponges to apply after each oath. If witnesses would watch policemen and other frequent oath takers, and follow their example of kissing the back of the hand that holds the book instead of the book itself, and would then keep their hands clean, they would be tolerably safe.

**To Suppress Quacks.**—The law upon the subject of quackery sorely needs strengthening in England, and the law, it has been not inaptly said, is made for the protection of fools, but that the man who is so incapable of using his own judgment as to fall a victim to the "confidence trick" should receive police protection, whereas another man who is foolish enough to become the prey of the "faith-healer" receives no protection at all, is an anomaly which can only be described as ridiculous.—*The Medical Times and Hospital Gazette*, September 16th.

**New Method of Massage.**—A German doctor has, according to the *Scientific American*, devised a plan for massaging rheumatic joints. He takes the patient's hand and puts it in a deep glass which is two-thirds full of quicksilver. The mercury exerts an equal pressure on every portion of the fingers, and the pressure increases rapidly as the fingers sink further into it. The hand is alternately plunged and raised about twenty or thirty times at each treatment, and after a second visit there is a marked diminution of the swelling.

**Marriage Rate in Australia.**—In 1897 the average marriage rate per thousand in the whole of Australia was 6.58. The average marriage rate of New South Wales was 6.72, that of Victoria 6.34, of Queensland 6.05, of South Australia 5.40, of Tasmania 6.22, of New Zealand 6.83. From this it will be seen that the New South Wales marriage rate, although slightly below that of New Zealand, is the highest in Australia, an unerring criterion of the prosperous condition of the colony.—*Public Opinion.*

**Acclimatization in Cuba.**—A correspondent writing to the *Boston Medical and Surgical Journal*, October 12th, says: "In my opinion, there is no such thing as acclimatization in Cuba for North American soldiers; a few months, or even a year or two, will give them no immunity whatever against tropical diseases, and may benefit them only by teaching the absolute necessity of temperate habits. Only one thing immunizes against yellow fever, and it is an attack of the disease. Malarial fever prevails all over the province, and no white or colored American soldier is safe against it; it decreases somewhat in the winter months, but much less than had been expected, while altitude, if more than three hundred or four hundred feet, has a distinct effect upon it. All American troops coming to Cuba, at any season, will suffer more or less from malarial fever and other tropical diseases, especially if camped under canvas, being then exposed to many great and sudden changes of temperature; thus, during the winter, the Fifth Immunes, in tents, had a rate of sickness at least twice as great as that of the Fifth Regulars, in barracks. It seems possible, by building comfortable barracks on high and salubrious sites, to reduce malarial fever to a minimum of three or four per cent. As to yellow fever, it may break out in any town in spite of all ordinary precautions, and soldiers can avoid it only by remaining in the country, either in barracks or in tents."

**A Sensible Suggestion.**—PHYSICIAN IN COUNTRY: "I don't know just what to advise for such a horrible-looking nose. You had better go to the city and consult a specialist." PATIENT WITH THE ROSACEA: "I am ashamed to travel with such a red nose. You cure me first, and then I will go."

**The Tsetse Fly.**—The much-dreaded tsetse fly which has interfered so seriously with the colonization of whole tracts of South Africa, is now known not to be the direct cause of the disease which follows its puncture, but to be the means by which the organism which causes the disease is introduced into the body. In this respect the tsetse fly resembles the malarial mosquito. It is not known whether the organism—hæmatozoon—passes through any of the stages of its life history within the body of the fly, or whether the proboscis of that insect acts merely as an inoculating needle.—*British Quarterly Review.*

**Treatment of Alcoholism by Inhibition of Alcohol and Massage.**—In *The Medical and Hospital Gazette* is an account of six cases of alcoholism treated successfully by inhibition of alcohol, by massage, and bromides. In the first place, it is instructive to note that this form had excellent results, and secondly, to remark upon the fact that out of the six cases treated half of that number were women. It is said that in the tropics both men and women have the tendency to become confirmed drunkards, the reason for this, it is explained, being want of exercise, ennui, and a general enervation of the system. Another reason probably is that Europeans generally, and the British in particular, will not adapt themselves to that mode of living most suitable to the climate.

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended December 1, 1899:

| | | Cases. | Deaths. |

### DIABÈTE BRONZÉ AND THE PATHOGENESIS OF DIABETES MELLITUS; ILLUSTRATED BY A CASE OF BRONZE DIABETES PRECEDED BY BASEDOW'S DISEASE.[1]

BY HENRY W. BERG, M.D.,

NEW YORK,

ATTENDING PHYSICIAN TO THE WILLARD PARKER HOSPITAL; ADJUNCT ATTENDING PHYSICIAN TO MT. SINAI HOSPITAL.

DIABETES MELLITUS is a disease, the importance of which is in direct proportion to its frequency. While we know much of its clinical history, less of its chemical physiology, and little of its pathology, even this meagre knowledge has been attained at the expense of the most persevering labor on the part of many competent investigators. That the data attained are so unsatisfactory is the result of the fact that the organs and functions, to the disturbance of which diabetes mellitus is due, are of so complex a nature that their investigation even under normal conditions is difficult. These difficulties are enormously increased in disease. This is true of the affection in its typical clinical manifestation. The case I am about to present, although of intrinsic interest on account of its complications, will repay study because, as I shall attempt to show, its complications serve to throw some light upon the nature of typical cases of sugar diabetes. The patient is one who suffers from diabetes mellitus, hypertrophic cirrhosis of the liver, bronzing of the skin, and exophthalmic goitre.

The history is as follows: Mrs. X——, forty-four years of age, German, married, admitted into Mt. Sinai Hospital May 16, 1899. Family history negative.

Previous history: Menopause one and one-half years ago; no children; no abortions. She was always very nervous. Nine years ago she had an attack of neurasthenia, with exophthalmic goitre, for which she was treated for a short time by Dr. Mandel, of Berlin. Electricity was used without relief; but she improved considerably under hydrotherapy (hot packs). She gained in weight, and was fairly well after this until the onset of the present disease six months ago. She has not been fond of starchy food or sugar in diet. She gives no history of any extraordinary fright or excitement.

Six months ago she began to suffer from severe thirst. She drank much water and passed a correspondingly increased quantity of urine. She began to lose flesh, and began again to suffer from cardiac palpitation. At present she has very severe thirst. Her appetite is ravenous, and she eats large amounts at all meals. She has no cough and no pain in the chest. She complains chiefly of emaciation, thirst, dryness of the mouth and throat, and great weakness. She says that there has been a gradually increasing blotching of the face for the past two years.

Examination: Her general physical condition is poor. There are signs of recent emaciation. Exophthalmic goitre—thyroid enlargement very slight, exophthalmos fairly marked, with tachycardia. Skin—brown pigmented patches, surrounded by white atrophic areas of skin interspersed with small pale brown spots on the left side of the face, the dorsum of both feet, and over the navel and left hip. There is no pigmentation on the lips or the mucous membrane of the mouth or palate. The tongue is dry and cracked. The liver is increased in size, and extends from the sixth intercostal space to two fingers' breadth below the free border of the ribs. Abdomen—all viscera easily palpable; spleen negative, not enlarged. Lungs negative. Heart—apex beat in the fifth space, nipple line, left border just within the nipple line; heart sounds negative. Urine cloudy, acid, specific gravity 1.020, and trace of albumin; five per cent. sugar; no acetone. Weight, sixty-three pounds. Eyes, examined by Dr. Gruening, negative. The patient does not perspire; she has not done so since sugar was noted in the urine, although formerly she perspired profusely. The patient was put upon an antidiabetic diet, and the administration of heroin, gr. $\frac{1}{12}$ every three hours, by Dr. M. Manges, into whose service she entered the hospital.

May 21st: No albumin; three per cent. of sugar; no diacetic acid; faint trace of acetone. In order to avoid what is for the purpose of this paper unnecessary detail in this portion of the history, I shall tabulate separately the result of examination of the urine from day to day.

NOTES TAKEN FROM THE EXAMINATION OF THE URINE OF MRS. X——, FROM MAY 18 TO OCTOBER 1, 1899.

She was treated at first with strict diet; later on, the patient having lost weight, and the sugar in the urine increasing in quantity, crackers and bread were given instead of gluten bread. The drugs used were the successively alkaline treatment, nitrate of silver, the salicylates, extract of thyroid gland, and opium, with no striking change either in the urine or the general condition of the patient.

June 7th: Pulse, 102; respiration, 26; temperature, 99.8° F.; weight, 61¼ pounds.

June 9th: She complains of severe pain in the

[1] Read before the Section on Practice of Medicine, New York Academy of Medicine, November 21, 1899.

course of the anterior tibial nerve (anterior surface of leg). The patellar reflex is absent; no ankle clonus. The pupils react to light and accommodation. There are no disturbances of sensation, no paralytic or paretic phenomena. For this pain galvanism was used, which gave some relief; similar pains in the arms were relieved by the faradic current.

July 14th: The patient has slight œdema of the ankles. This lasted until July 20th, when it disappeared in the ankles, but remained on the dorsum of the foot.

The patient came under my care July 24th. She was passing, at that time, large quantities of urine containing five to seven per cent. of sugar; acetone was present. She was extremely emaciated. She had several attacks of diarrhœa, which were checked by treatment. There was swelling of the dorsum of the

Fig. 1.

feet and lower part of the legs. The longitudinal branches of the superficial abdominal veins, the superficial epigastric and its branches were very prominent and enlarged, extending upward over the free border of the ribs, and downward over the anterior surface of the thighs, not forming a caput medusæ, however, around the navel. The eyeballs were prominent, and the pupils normal. The thyroid enlargement was slight. Liver—the left lobe comes down three inches below the xiphoid cartilage in the median line; the lower border is easily mapped out. The right lobe of the liver is two fingers' breadth below the free border of the ribs in the nipple line. The free border of the liver is painful when palpated. The bronzed discoloration of the skin extends over the whole of the left side of the face under the chin, and to the right side of the face. There is a small circle of pigment over the umbilicus. There is a large patch over the sacrum and both trochanters. There is bronzing over the labia, mons, and the internal surface of both thighs. There are bronze patches interspersed with normal skin over the dorsum of the left arm and left forearm. The bronzed areas are of a deep brownish-red color. Here and there over the arm are small leucodermatous spots. The epidermis over these areas does not scale. A scraping taken from the epidermis over these bronzed areas did not show on microscopic examination the microsporon furfur. A blood count made September 13th showed: red cells 4,832,000, white cells 5,200, hæmoglobin seventy-five per cent.

The patient was under my care about two months. She was treated with pancreatic extract, by high injections into the rectum, salicylates, and iron. During that time she increased in weight to sixty-nine pounds, which was her weight September 19th. Since that time she has been under the care of Dr. Rudisch. During the past few weeks the patient has developed extensive œdema of both lower extremities, general ascites, and anasarca, together with an attack of pulmonary œdema. Even the face was œdematous. She is at present in the service of Dr. Rudisch. Under his care these threatening complications have again subsided, and the patient, as I am told by the house physician, is *in statu quo*.

A review of the salient points of the history of this case shows:

1. A patient who some years ago suffered from exophthalmic goitre, from which she still suffers, the goitre, however, being markedly diminished.

2. A subjective history of diabetes mellitus, which, when the patient comes under our observation, is found to include all of the objective and subjective symptoms of sugar diabetes of a severe and progressive type.

3. A bronzed discoloration of the skin, chiefly marked on the face, chin, forearms, external genitals, and inner surface of the thighs.

4. A fairly well-marked hypertrophy of the liver, with enlargement of the superficial cutaneous veins of the abdomen and slight temporary œdema of the feet and legs while under my observation, but since then marked œdema and ascites, which I should ascribe partly at least to the hypertrophic cirrhosis of the liver.

Upon these data I have recognized this as a case of a condition first described clinically and pathologically by Hanot and Chauffard, and called by them "diabète bronzé"—a diabetes accompanied by more or less general bronzing of the skin and hypertrophic cirrhosis of the liver, complicated in our case by a coincident exophthalmic goitre. This combination of the two conditions in the same patient, namely diabète bronzé and exophthalmic goitre, partly from its rarity, but above all because of the clew which it gives to the pathogenesis of diabetes mellitus, renders a study of the case extremely instructive.

Diabète bronzé is still so rare, less than twenty cases (fourteen autopsies) having been recorded in literature, that a short résumé of what is known concerning this condition will not be out of place.

In 1882 Hanot and Chauffard[1] reported two cases, clinical histories and autopsies with microscopic sections of organs, illustrated, in which diabetes was combined with pigmentation of the skin, liver, and other organs. In this first paper Hanot gave a graphic and accurate description of the clinical history and pathology of these interesting conditions. In 1886 Hanot and Shachman[2] described two other cases and called the disease by the name of diabète bronzé. Since Hanot's first paper about fourteen cases have been reported by various observers and about eight or ten cases without autopsies. For all of these, Hanot's first description seems to have been wonderfully complete, although the views first expressed by him, and held up to 1896[3] concerning the pathology and the pathogenesis of the various phenomena which characterize the disease, have given rise to considerable discussion on the part of some of the best French authorities. In all of these cases the liver was enlarged; the enlarge-

ment was slight or considerable, the organ weighing in Hanot's cases from 1,800 to 3,500 gm. In his earlier cases the liver was very large; in the later cases, 1886, the enlargement was very slight. He found that there may or may not be the symptoms of disturbances in portal circulation; that when ascites is present it is usually slight; there may be œdema of the legs without ascites; and there may be also temporary diarrhœa as seen in my case. All of these symptoms are probably due to disturbances of the portal circulation caused by the hypertrophic cirrhosis of the liver. The bronzing of the skin is more or less general, chiefly located on the face and neck and arms, external genitals, and upper surface of the thighs. Naunyn and Hanot both report a case of diabetes in which the hypertrophy of the liver and the bronzing of the skin seemed to increase in like proportion. The spleen was sometimes found to be hypertrophied, but generally not enlarged.

At autopsy the hypertrophied liver is found to be smooth externally, rather dense on section, of an iron-rust color. The bilè ducts as a rule are unaffected. The spleen is reddish-brown in color, indurated, and sometimes enlarged. There is a similar pigment discoloration in the pancreas, lungs, muscle of the heart, and in the kidney, and in one important case reported by Mossé[1] and Mossé and Daunic[2] there were found histological changes in the suprarenal capsules, alalthough macroscopically one could observe no gross changes in these organs. I shall speak further of this case later on. The pigment is distributed in the liver, where it has been studied most thoroughly by all observers, especially by Hanot and Chauffard, between the connective-tissue fibres, in the fibres themselves, and in the hepatic cells. Some cells contain few granules and some are so filled with the pigment granules that their nuclei are lost, the whole cell being changed into a reddish mass. This description would apply to the distribution of the pigment in the other organs in which it is found. In the skin, the pigment is present in the deepest layers of the cells of the Malpighian bodies and in the vascular network of the integument.[3] M. Rendu, in a discussion upon a paper by E. Jeanselme,[4] reported a case in which he said he had found no pigment granules in the circulating blood, and a careful search revealed no emboli in any of the organs. These negative findings are important in connection with the pathogenesis of the bronzing. M. Jeanselme[5] found that when the patient was subjected to the *x*-ray, the pigmented areas did not permit the passage of the light, and the bones appeared far less distinctly than those behind the normal skin. This is corroborative proof of the ferric nature of the pigment.

Before discussing the pathogenetic significance of these pigmentations and pathological changes it is proper here to call attention to the fact that a similar pigmentation to that found in diabète bronzé has been reported in a considerable number of cases of Basedow's disease, and since our patient suffered from Basedow's disease ten years ago, and fully eight years before the occurrence of her diabetes, it might be considered that the pigmentation is a symptom of the exophthalmic goitre. Thus Dr. David Drummond, quoted by Bramwell,[6] noted pigmentation of the skin in a considerable proportion of the cases of Graves' disease. Dr. Bramwell found it in twenty-nine cases out of seventy-nine.[7] Other authorities could be quoted to the same effect. Diabète bronzé, however, does not consist clinically in diabetes and bronzing of the skin, but in these symptoms combined with hypertrophic cirrhosis of the liver, and the symptoms ascribable to the latter condition and this combination, forming the symptom complex of diabète bronzé, are present in our patient. A scraping from the skin showed the absence of the microsporon furfur, which excluded pityriasis versicolor. The differentiation from other forms of pigmentation I shall speak of presently.

Of the conditions present in diabète bronzé two deserve here special consideration: (1) The nature, source, and pathogenesis of the pigment which gives rise to the bronze discoloration of the skin and organs. (2) The connection between the hypertrophic cirrhosis, mostly in the liver and to a less extent in the other organs, and the diabetes.

As to the nature of this pigment material all authorities—including Hanot—agree that it is due to the deposit of an iron-containing pigment. This has been shown post mortem and clinically, as regards the pigment deposited both in the organs and the skin, by the ammonic-hydric sulphate and the ferrocyanide test. Most authorities found it to consist of a ferric hydrate. M. Rendu quotes Kelsch and Kiener to the effect that the discoloration of the skin in malarial cachexia is due also to a ferric pigment. Brault[1] has shown that in certain non-diabetic pigmentary cachexias the discoloration is due to a similar iron pigment. Gilbert and Grenet have reported a case of hypertrophic cirrhosis, "pigmentaire sans diabète," in which pigmentation was of the same chemical constitution.

It is interesting to note that a similar unanimity does not exist with regard to the pigmentation of Addison's disease. Thus while Perls[2] obtained the iron reaction in the pigmented areas in this disease, and v. Kahlden[3] considers the ferric nature of the pigment most probable, Brault[4] has not found the iron reaction in the pigment of Addison's disease.

Now the reservoir of iron in the body is the hæmoglobin of the blood. There it exists in combination with the stroma of the red blood globules, and this connection must be broken up and the corpuscles destroyed before the hæmoglobin is set free. The hæmoglobin consists of a proteid body and an amorphous coloring matter, hæmatin, which latter contains all of the iron of the hæmoglobin; so that the bronze pigmentation of diabète bronzé is an example of hæmosiderosis. Now it becomes a subject for inquiry as to why this coloring matter in the shape of pigment granules thus derived from the blood is deposited in the various organs and skin in which it is found in diabète bronzé. This portion of the subject is enveloped in the greatest confusion, and all the more is this to be regretted since its proper solution would throw much light upon the relation of the bronzing to the diabetes and the cirrhosis of the liver. The views held by various authorities are as follows:

Hanot at first thought that a so-called chromatogenic function which he ascribed to the liver cells was stimulated, as a result of the diabetic endarteritis and the obstructed circulation caused thereby; thus there was a hypergenesis of pigment in the liver, carried throughout the body by the blood-vessels in the shape of minute emboli. Apart from the facts that the liver has no such function, and that such emboli would result in numerous infarctions, which as a matter of fact are not found clinically or at autopsy in diabète bronzé,

it is difficult to understand how pigment granules even finely divided could transude through the walls of the capillaries. Furthermore in the case cited above, reported by M. Rendu, no pigment granules were found in the blood-vessels and no emboli in any of the organs.

Brault and Gaillard[1] modified this view by supposing that the diseased (hypertrophic cirrhotic) liver was unable to utilize the degenerated blood pigment supplied to the hepatic cells in normal quantity, and that as a result the pigment accumulated in the circulation, and was thence distributed throughout the organs and skin. In other words, they thought that the pigmentation was secondary to the hypertrophic cirrhosis. This theory depends upon the known fact that the bile pigments are formed from the hæmoglobin or rather hæmatin of the blood. Were it true, however, we should expect to find that less bile than normal should be formed in diabetes. This I find von Noorden[2] and other authorities deny. M. Mossé,[3] who carefully studied very complete post-mortem findings in a case in which there were histological changes in the suprarenal capsules, considers the diabetes as primary, and that this causes the change in the blood and the production of the free pigment. This free pigment he conceived was deposited in the liver most extensively because the amount of blood circulating in this organ was correspondingly large. He thinks that the cirrhosis is the result of the perivascular changes which are caused by the sugar and free pigment circulating in the blood-vessels. Notwithstanding that in Mossé's case there were lesions of the suprarenals, he did not think that the bronzing was of the character of Addison's disease, chiefly for the reason that there was found no discoloration of the mucous membranes. These views of Mossé are similar to those of Massary and Potier.[4]

M. Rendu[5] very properly objects that if this pigment were set free in the blood under the influence of the diabetic cachexia and carried to the different organs where it is found post mortem, it would cause multiple emboli. He therefore believes that it is the result of "vicious elaboration" on the part of the protoplasm of the cells of the organs and tissues in which the pigmentation is found. He thinks the glandular cells in general, especially those of the liver and the cells of the cardiac muscle, are the most active in this respect. As soon as the pigmentary granules become very abundant they overcrowd and kill the cell. The pigment granules are then poured out in the adjoining tissues and taken up by the lymphatics, and carried throughout the body even to tissues where the pigment has not been previously formed. In other words, he considers the elaboration of this red pigment the manifestation on the part of the individual cells of the cachectic degeneration affecting the whole organism.

M. Letulle[6] thinks that the pigment found in the organs, heart, muscle, and skin is formed *in situ* from the hæmoglobin of the circulating blood or muscle. He thinks that all pigmentary cachexias are characterized by changes, similar to those found in diabète bronzé, in the liver, pancreas, heart, ganglia, etc.

M. Jeanselme[7] thinks that diabète bronzé is caused primarily by a destruction of the red blood globules taking place in the capillaries of the parenchyma. The iron-containing pigment thus set free is carried to the glandular organs. In the liver some of it is utilized for the bile. The excess of pigment remaining in the different cells gives rise by its irritation to the cirrhosis. If the cirrhosis affects the pancreas as well as the liver, diabetes results. The latter then he considers only an accidental epiphenomenon, the change in the blood cells the primary condition. He is led to think so because the red pigment is found deposited in the organs in other conditions well known to be accompanied by a destruction of red blood globules. It has been observed in the most diverse affections viz.: (1) diabète bronzé; (2) in paroxysmal hæmoglobinuria (case of Dieulafoy and Widal); (3) in the extreme anæmia of pseudo-leukæmia; (4) in hæmoglobinuria of bilious fever; (5) in chronic malaria. In all of these the pigmentation has been seen, and its distribution was similar to that seen in diabète bronzé. These views are concurred in by Albert Lenné.[1]

M. Hayem[2] agreed with the view that the pigment was formed *in situ* in diabète bronzé and not carried there by the blood current.

At present Hanot[3] agrees with Marie[4] that diabète bronzé is not a mere modification of diabetes or, in other words, diabetes with pigmentary cirrhosis of the liver, nor a cachexie bronzé, but a true pathological entity. They consider it, in fact, a new disease of which the pathology is not yet understood.

For a proper conception of the manner in which this bronzing is formed and deposited in the locations in which it is found after death the following data are instructive. In the first place, as has been seen, the pigment is undoubtedly derived from the hæmoglobin of the blood globules. Secondly, the blood of diabetes has two characteristics which are of interest to us in this connection: (*a*) It contains a much larger percentage of glucose than normal blood—normal blood containing 0.05 to 0.15 per cent. of sugar, while in diabetes mellitus the blood contains about 0.57 per cent.[5] The percentage naturally varies under conditions of fasting and varieties of foods, etc., but the figures given show the large increase of sugar in the blood of diabetics. (*b*) Grawitz[6] explains that, as Brasoe[7] has shown, when sugar is introduced into the circulation in animals it causes a passage of fluids from the tissues into the blood-vessels, producing primarily a dilution of the blood and a distention of the blood-vessels. It is this augmentation of the volume of blood which causes the polyuria, which in turn causes a secondary concentration of the blood. But for the present it is important for us to remember that there is primarily a large dilution of the blood and that it contains a very much increased percentage of sugar. Now even on the laboratory table it can be shown that adding water to blood dissolves out the hæmoglobin from the red blood globules; or, in other words, the connection between the stroma and the hæmoglobin in the red blood corpuscles is broken and the hæmoglobin set free.[8] It appears to us also that the increased specific gravity of the plasma due to the sugar has a similar effect. Hæmoglobin is very soluble in blood serum, and when thus set free in the living capillary under the influence of the presence of sugar and increased dilution of the blood, it remains dissolved in the serum. When thus in solution in serum hæmoglobin diffuses very readily. Under the influence of the increased tension of the capillaries due to the distention with blood abnormally diluted with a watery solution of sugar, the kidneys are stimulated to hyperactivity, and as a further aid toward the decrease of excessive volume of the blood, serum from

the vessels diffuses into the perivascular spaces. This serum, as we have already shown, contains hæmoglobin in solution, which remains deposited in the tissues and cells, and when decomposed forms the iron pigment granules which cause the hæmosiderosis. This process is frequently duplicated at the bedside, when the surgeon does a venous infusion with a decinormal salt solution, in cases of severe hemorrhage. Here the volume of the blood is increased by the injection of a decinormal salt solution instead of, as in diabetes, a sugar solution, and frequently as a result there is temporary hæmoglobinuria and pigmentation of various portions of the integument. In this therapeutic procedure, these symptoms, while more acute, as is shown by the hæmoglobinuria, are temporary, while in diabète bronzé, and probably in other "bronze" conditions, the cause is a lasting one and the bronze pigmentation of the skin becomes deep and permanent. The anæmia which should accompany this condition of the blood in diabetes is cloaked by the secondary increased concentration of the blood produced by the polyuria and transudation into the perivascular spaces. This explains why writers on diabetes differ as to the results of blood counts made of blood from diabetic patients. Some authorities report a very large diminution in the number of red blood globules, some report a normal number of these (Grawitz).

I have quoted the case of Mossé [1] in which a case of diabète bronzé showed post mortem a lesion of the adrenals when microscopically examined. This case and other considerations might suggest that the bronzing in these patients was due to the same causes as in Addison's disease. I have already stated, however, that the bronzing of Addison's disease affects the mucous membranes in every case, while in diabète bronzé the mucous membranes are never involved. In addition to this, the pigmentation of Addison's disease, while containing iron, contains also other pigment matters and their proteids. The pigment granules are not deposited in Addison's disease as granules in the internal organs and secreting cells, as is shown particularly in the liver, in diabète bronzé. Dr. McMunn[2] says: "The adrenals remove from the circulation useless and worn-out pigments and their proteids. If disease affects the adrenals these pigments are left circulating in the blood, producing pigmentation of the skin and mucous membranes as in Addison's disease." He does not support this theory of the function of the adrenals by any trustworthy data.

The cirrhosis of the liver appears to me to be secondary to and developed with the pigmentation. It is true that the liver in diabetes is the seat of a hypertrophy and induration in a very large proportion of all diabetics, but most authorities at the present time attach little importance to this as far as the pathology of diabetes is concerned. Glénard found hypertrophy of the liver in about thirty-five per cent. of his cases. In forty per cent. he found induration. Von Noorden found enlargement and induration of the liver in about twenty-two per cent. of his cases. Rauch found a normal liver in only about twenty-two to thirty-nine per cent. of all the autopsies upon diabetics. This hypertrophy and induration, however, are not at all comparable to the hypertrophic cirrhosis seen in cases of diabète bronzé. This condition is produced in these patients, it appears to me, as a result of the formation of pigment granules in the cells and connective tissue of a liver suffering from ordinary diabetic engorgement. The slowness of circulation which accompanies this latter condition encourages the transudation of serum containing free hæmoglobin in solution, of which we have just spoken, and adds a further causative factor why pigment is deposited in the liver in greater quantity than in the other organs. The hypertrophic cirrhosis of the liver thus produced helps, by obstructing the portal circulation, to retard the venous return from the pancreas and other abdominal organs and glands, and thus aids in the deposit and formation of pigment granules in these organs, glands, and even more distant tissues like the skin and heart. Similar, although much less marked cirrhotic changes occur in the tissues and cells thus the seat of these pigment deposits. I consider, then, the pigmentation of diabète bronzé as due to a deposit of iron pigment, derived from the hæmoglobin of the blood, which, derived from the blood globules under the conditions I have described, comes to be dissolved in the blood serum. In this form it transudes into the perivascular spaces and organic cells of the viscera, heart muscle, and skin, and remains deposited when the serum in which it is in solution is again taken up by the capillaries.

We now come to consider another condition present in our patient, the Basedow's disease, and inquire into the relation which it bears to the diabetes. For this purpose we must turn our attention to the pathogenesis of diabetes. The sugars and starches included in the group of carbohydrates of the food may, for the purposes of this paper, be represented as undergoing digestion in the alimentary canal, in which, under the influence of certain ferments derived chiefly from the salivary glands, pancreas, and intestinal glands, they are changed to glucose, an easily diffusible form of sugar. In this form they are taken up by the portal circulation and pass to the liver, in which they are stored up in the form of glycogen. So great is the storing capacity of the liver for this material that it sometimes represents as much as fourteen per cent. of the weight of the organ.[1]

From the glycogen thus stored up, the liver again converts to glucose a quantity sufficient to supply a fixed percentage of glucose to the venous blood passing from it. Thus glucose enters the circulation in what is practically a fixed percentage, varying from 0.05 to 0.15 per cent. in man. Some of this grape sugar in the blood is again converted into glycogen in the muscles and stored in them, for use in the production of energy. By far the larger proportion, however, is, according to Lepine,[2] destroyed by a glycolytic ferment formed in the pancreas. When this latter organ is extirpated, or at least removed to the extent of ninety per cent. of the organ, or so diseased that the ferment is not produced, the grape sugar in the blood is not destroyed, accumulates in excess, and is excreted by the kidneys. Thus glycosuria results.

Diabetes mellitus, then—I do not here include the temporary glycosuria which follows the eating of carbohydrates in excess—may be due to disease or interference with the saccharine functions of the liver, or disease or interference with the glycolytic action of the pancreas. Furthermore, the famous experiments of Claude Bernard showed that in animals puncture of the apex of the calamus scriptorius in the floor of the fourth ventricle caused glycosuria, lasting many hours. When the animal was killed, after the glycosuria had ceased, it was found that the liver was free from glycogen. In other words, the puncture of the medulla at the above-mentioned point had caused the liver to yield up all of its store of glycogen to the circulation in the shape of glucose, which had been excreted by the kidneys as grape sugar in the urine. Many other lesions of the nerves, ganglia, and nerve centres produce a similar effect, although not with anything like the constancy with which the lesion of the medulla

[1] Congrès de méd. et d'hyg., 1894, p. 777.
[2] British Medical Journal, February 4, 1888, p. 233.

[1] Von Noorden "Die Zuckerkrankheit."
[2] "Le ferment glycolytique et la pathogénie du diabète," Paris, 1891.

causes it. Thus this effect was found to follow destruction of the upper and lower sympathetic cervical ganglia, the first thoracic ganglion, and the abdominal ganglia of the sympathetic. Here then we have three possible varieties of glycosuria:

1. The glycosuria resulting from disturbance of the function of the liver.

2. The glycosuria resulting from disturbance of the function of the pancreas.

3. The glycosuria due to puncture of the medulla resulting in the yielding up by the liver of the store of glycogen, with a probable simultaneous stoppage in the secretion of, or at least no corresponding increase in, the secretion of the glycolytic ferment in the pancreas.

Clinically, however, cases of diabetes do not always show post-mortem lesions of the liver, or lesions of the pancreas, or lesions of the medulla, or any of these. What, then, is the connection between these different pathogenetic factors in the production of diabetes with each other and with the disease? A study

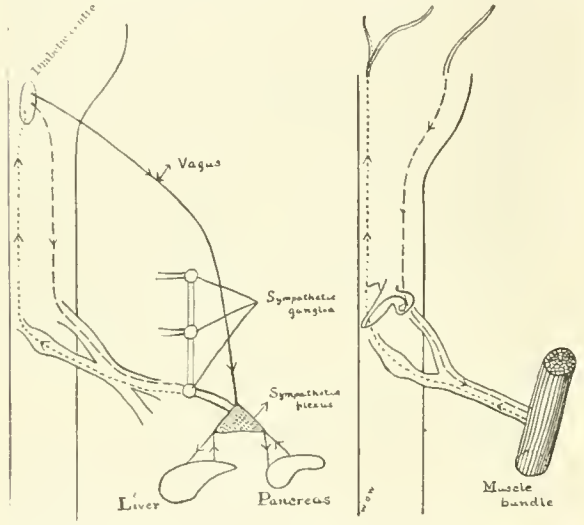

FIG. 2.—Schematic Representation of Probable Course and Distribution of Visceral Motor and Sensory Nerves. ..... Gray ramus communicans; - - - - - white ramus communicans.

of the nervous mechanism which governs the functions of the liver and pancreas will serve to throw some light upon this question.

As is known, all of the viscera, including the liver, the pancreas, and suprarenals, are supplied by nerves derived from the sympathetic system as well as from the cerebro-spinal system. In the case of the liver and pancreas, however, the nerves derived from the cerebro-spinal system reach these organs both through branches from the pneumogastric sent directly to the large sympathetic plexus in the abdomen, and indirectly, through the gray and white branches which pass from the sympathetic ganglia and their connecting sympathetic cords arranged along the front of the entire length of the vertebral column, to the anterior primary division of the spinal nerves. These communicating branches between the spinal nerves and the primary sympathetic nerves and ganglia are known as the gray and white rami communicantes. So that the large sympathetic plexus in the abdomen, such as the epigastric and splenic plexus, from which emanates the nerve supply of the liver and pancreas, contains, first, purely sympathetic nerves mostly non-medullated and taking their origin in the numerous sympathetic ganglia; second, the cerebro-spinal fibres derived from the anterior primary divisions of the spinal nerves; third, fibres coming directly from the pneumogastrics (left pneumogastric to hepatic plexus, right pneumogastric to splenic plexus).

It must not be forgotten here that the secreting cell, just as the muscle cell, is provided with sensory fibres, motor fibres, and trophic fibres, the special nerves of nutrition for the cell.

The sensory fibres, as in the muscular system, are afferent, passing from the visceral cell through the sympathetic nervous system to the spinal cord, and thence to the centres in the cord chiefly through the gray ramus communicans.[1] These afferent fibres carrying sensory impressions centripetally go with great directness from the viscus to the cerebro-spinal centres, passing through very few, if any, ganglionic stations, differing in this respect from the motor, secreting, or dynamic fibres of the visceral cell, which reach these cells after having passed through many sympathetic ganglia, in their course from the spinal cord to the sympathetic plexus, and after having formed the most extensive connections with other nerve fibres derived from the sympathetic and cerebro-spinal nervous systems. These sensory fibres of the visceral cell do not carry sensations of pain, heat, touch, etc., only, to the cerebro-spinal centres, but sensations of a more complex character peculiar to each viscus, which indicate the need on the part of the organism for the peculiar motor or rather secreting activity of the visceral cell. So that secretion is a function of a glandular cell, which is the reflex manifestation of a peculiar sensibility in these cells. As I have already indicated, secretion is the manifestation of a glandular cell just as motion is that of a muscle cell. These secreting or rather motor impulses are carried to the viscera from the cerebro-spinal centre through two paths: First, through the spinal cord, spinal nerves, white rami communicantes, sympathetic ganglia and trunks, to the sympathetic plexus, and thence distributed to the viscus; second, through a cerebro-spinal nerve (in the case of the liver and pancreas, the pneumogastric nerve) to the sympathetic plexus, and thence to the viscus. These two separate paths are intended for the transmission of two distinct kinds of motor (secreting) impulses, the one the complement of the other, some physiologists even think the antagonist of each other. I am led to adopt the view hinted at by Morison,[2] that the motor fibres passing from the centre through the cord to the white ramus communicans and sympathetic ganglia and nerves store up some of their motor activity in these ganglia, which are thus rendered capable of causing constant secreting activity on the part of the glandular cells connected with them, while the motor (secreting) fibres passing through the cerebro-spinal nerve (vagus in the case of the liver and pancreas) carry a reflex impulse to the cells, preventing this constant activity except when necessary. Upon this theory we could explain why puncture of the floor of the fourth ventricle at the lower portion of the motor nucleus of the vago-glosso-pharyngeal nerve and its spinal accessory branch produces mellituria, namely, by irritation of motor sympathetic fibres passing down the cord, while section of the vagus fibres removes the controlling influence of the vagus. This would also explain why the mellituria occurs even when both pneumogastric nerves have been divided. We need not, for our purpose, enter into the question of the further connection between this nucleus in the medulla and the higher cerebral and cerebellar centres. For our purpose the tracing of the connection between the nerve supply of liver cell and pancreatic cell on the one hand and the centre in the medulla on the other is sufficient. Indeed, I have ventured upon this brief résumé of these salient factors in the anatomy and physiology of the nervous mechanism of the liver and pancreas and incidentally of other abdominal viscera, not with any idea of giving a complete or even accurate account of the subject,

[1] Kölliker: "Gewebslehre," p. 862.

[2] "The Nervous System and Visceral Disease," London, 1899.

for even the most advanced knowledge and data obtained from the writings of the most competent anatomists and physiologists cannot be termed complete or accurate; for in this field knowledge is extremely limited, and much of what is known is vague—but I believe the known data are sufficient to enable me to draw a clinical parallelism between disturbances of functional activity in a muscle cell or fibre resulting in paralysis and disturbances in the functional activity of cells of the liver and pancreas which result in diabetes mellitus. And here I would call attention to the fact that, considered from their connection with the formation and destruction of glucose in the animal economy, the liver and pancreas are ductless glands. It is true that the liver has ducts for the discharge of the bile which it secretes, but the glycogen which it stores up is formed from the glucose supplied by the portal blood, and the glucose into which it is transformed by the liver is carried from that viscus by the circulation. So also, although the pancreas has a duct through which it discharges the pancreatic juice, the glycolytic ferment is formed in the pancreas from the blood and discharged into the circulation, where it meets with the glucose upon which it exerts its activity. The consideration of the pancreas and liver as ductless glands is interesting in this connection, from the fact that in many of the diseases of the ductless glands, such as diseases of the thyroid, Graves' disease and myxœdema, of the suprarenal capsules, Addison's disease, disease of the pituitary body (acromegaly), the sympathetic nerves and plexuses have been found involved, having been found the seat of degenerative changes in many autopsies. It will be remembered that when a muscle is paralyzed the paralysis may be due to: first, disease of the muscle cells forming the fibres with a corresponding loss of their essential motor irritability; second, it may be due to destructive changes of the motor nerve supplying it, such as a neuritis; third, it may be due to destructive changes in the motor-nerve tracts in the spinal cord; fourth, it may be due to destructive changes in the gray centres in the spinal cord; fifth, it may be due to destructive changes in the motor-nerve tracts between the spinal cord and cerebral centres; sixth, it may be due to destructive lesions of the cerebral centres or cortex. A lesion of the sensory nerve connecting the muscle cell with the centre in the spinal cord will give rise to disturbance in the reflex motor manifestations of the muscle cell. This is a schematic outline sufficient for our needs of the various lesions, all of them manifested by a loss of the motor activity of the muscle cell. I have spoken of destructive lesions because I have mentioned paralysis of muscles. Equally multifarious irritative lesions, all resulting in a similar spasm of the muscle fibre, could be recounted. The important fact to remember is that the peripheral manifestation of disturbed function in the muscle cell is the same irrespective of what portion of the nerve tract is the seat of the lesion, the disturbance being of a paralytic or spastic character depending upon whether the lesion is irritative or destructive. So also what I have already said of the general principles governing the anatomy and physiology of the nerves of the viscera has shown that disturbances of visceral function may be due, first, to destructive or irritative lesions of the visceral cells; for the secreting cells, like the muscle cells, possess their essential secreting irritability.[1] Second, such disturbance may be due to lesions of the visceral motor nerves (plexuses, sympathetic nerves, and ganglia, white ramus communicans, and spinal branches). Third, they may be due to lesions of the sympathetic motor paths in the spinal cord. Fourth, they may be due to lesions of the cerebro-spinal branches of the sympathetic plexus. Fifth, they may be due to lesions of the centres in the medulla and upper portion of the cord. Sixth, finally, a disturbance in the reflex visceral activity may be due to lesions of the sympathetic sensory or afferent branch of the viscus. I have purposely not traced the visceral nerve impulses higher than the medulla because for schematic purposes this knowledge is too vague to be considered. That there is a control exercised on the part of higher cerebral centres through nerve paths, which are undetermined, over the functional activity of the viscera is positive. One other point of similarity between disturbances of motor activity of muscles and functional activity of viscera is that in both cases a destructive lesion of any portion of the efferent or motor-nerve path results in degenerative changes extending from the lesion toward the periphery in those nerve fibres and trunks which have been separated from the trophic nerve centres, so that while muscles and viscera supplied by branches given off from a motor-nerve tract centrally to the lesion retain their functional activity, those supplied from the degenerated portion of the nerve trunk, peripheral to the lesion, lose their power of functional activity. While the course of viscero-motor impressions in the viscero-motor tracts passing from the centre to the periphery is much more indirect than that of musculo-motor impressions, the viscero-motor nerves being interrupted in frequent ganglia and plexuses, the trophic influence of which upon nerves passing through them is not sufficiently understood, these general considerations will serve to show that similar principles of localizing the lesions—which are the cause of disturbances in visceral function—obtain as those which we are accustomed to use in the localization of lesions causing paralysis or spasm of muscles.

Applying this dictum to diabetes mellitus, the visceral disease to which this study is devoted, the disease may be due to, first, disease, irritative or destructive, of the pancreas and liver as viscera; second, to destructive or irritative lesions of the sympathetic motor nerves supplying the pancreas and liver, the ganglia with which they are connected, and plexuses from which they are derived; third, it may be due to irritative lesions of the sympathetic motor paths in the spinal cord connecting with the large plexuses in the abdomen through the lumbar rami communicantes; fourth, diabetes mellitus may be due to a destructive lesion of the cerebro-spinal nerve, the vagus, supplying the liver and pancreas; fifth, diabetes mellitus may be due to lesions of the lower portion of the vagal centre in the medulla; sixth, finally, it may be the reflex manifestation of a lesion of the sensory sympathetic extending from the liver and pancreas through the gray rami communicantes to the cord, and thence to the medullary centre. One or more of these factors may be present in a given case of diabetes mellitus, depending upon the character and extent of the disease producing the lesions. Many cases of diabetes mellitus have been examined post mortem, which have shown lesions in several of these locations.

Thus, for example, I have already spoken of the frequency with which the liver is found enlarged in patients suffering from diabetes mellitus. Von Noorden reports 3.8 per cent. of his cases as suffering from cirrhosis (atrophic) of the liver. One of these cases was a syphilitic cirrhosis. Rauch[1] found at autopsy normal liver in only sixty to seventy-five per cent. of all cases. The diseases found were hypertrophy, congestion, and fatty degeneration. It is to be noted that large tumors, abscesses, and cysts of the liver are only seldom accompanied by diabetes; the reason probably being that in these cases sufficient of the viscus retains its integrity to perform the necessary function of converting sugars; while hypertrophy, congestion, and

[1] Morison: *Op. cit.*, p. 36.

[1] "Lipaemia bei Diabetes Mellitus," Leipsic, 1895.

fatty degeneration, involving as they do the whole organ, are more apt to cause diabetes. The pancreas is frequently found diseased in diabetes. Most frequently are found sclerosis, atrophy, fatty degeneration, and necrosis of the cells; occasionally are found cysts, stone in the duct, carcinoma, and echinococcus. Experimentally it has been shown that if ten per cent. of the pancreas remains glycosuria will not appear, which also explains why extensive disease of the pancreas may be present without diabetes. Syphilis and tuberculosis of the liver and pancreas have been found in diabetics, while frequently these conditions have been present without sugar in the urine. It is evident that the occurrence of diabetes as a sequence of all of these conditions of the liver or pancreas depends upon the fact whether sufficient of the viscus in question has been destroyed to interfere with the proper performance of the sugar function—if I may so call it.

Taking up now the possible lesions on the part of the nerves and nerve centres which might cause diabetes, in pursuance of the scheme outlined above, it is, first of all, of interest that as far back as the first experiments by Claude Bernard on the medulla in the production of diabetes, it was found that glycosuria did not follow the puncture of the medulla if this operation was preceded by section of both splanchnic nerve trunks. Furthermore, experimentally, glycosuria followed extirpation of the first and second cervical ganglion, or the first dorsal ganglion of the sympathetic[1] caused glycosuria by exsection of the cœliac ganglion and plexus. Pathologically, lesions of the sympathetic have been frequently found post mortem in diabetes; thus Ponikle[2] reports three cases of disease of the abdominal sympathetic accompanying diabetes. Hale White reports four cases of sclerosis of the semilunar ganglia and plexus. Kulz and Koch (Naunyn) report two cases of unilateral perspiration with contracted pupils on the affected side in which there was diabetes accompanied by a probable lesion of the sympathetic. The vagus has also been found involved with diabetes; thus Newman has three cases of tumor of the vagus nerves accompanied by diabetes. The lesions of these nerves, plexus, and ganglions are not necessarily gross lesions, such as tumors, but may consist of the various forms of neuritis, syphilitic, tuberculous, toxic, alcoholic—indeed all inflammatory and degenerative forms of neuritis. The spinal cord has been found diseased, especially in its posterior columns, in cases of diabetes with rather more frequency than other portions of the cord. This is interesting in connection with the frequent absence of the patellar reflex in diabetics. Souques and Marinesco,[3] in a paper entitled "Lésions de la moëlle épinière dans un cas de diabète sucré," report a case in which they found a symmetrical pale zone of degeneration in each posterior column of the cord. This patient had suffered from diabetes with Basedow's disease. Nonne[4] reports a case of poliomyelitis anterior chronica, with the characteristic lesions in the gray horns, accompanied by diabetes. Kalmus,[5] Leichtentritt, Lepine, and many others report cases of spinal-cord lesions with diabetes. Equally numerous are observations of lesions in the medulla and cerebrum, accompanying diabetes. My object here is not to give the symptoms which will enable us to localize the lesion in a case of diabetes mellitus, for the pathological material is not yet sufficiently extensive to justify systematic differentiation in this direction, but rather to indicate my belief that diabetes mellitus is the result of a disturbance in the function of the liver or pancreas, or both, dependent upon either disease of these viscera or disease of the nerves, sympathetic or vagus, which supply them, or disease of the sympathetic ganglia, or disease of nerve paths in the spinal cord which connect these sympathetic nerves with the centres in the medulla, or disease of the medullary centre, or the nerve paths and higher cerebral centres with which the medullary centre is connected. The lesions may be of any character, inflammatory, syphilitic, tuberculous, toxic, with which we are familiar in pathology, and the success in the treatment and prognosis of diabetes mellitus will depend upon our knowledge of the pathological nature of this lesion and its location in any given case.

It is evident that in an individual case of diabetes the localization of the lesion causing the diabetes, in the abdominal sympathetic, would be aided by the demonstration of the simultaneous presence of other clinical phenomena which are generally ascribed to lesions of the sympathetic. The case of diabète bronzé reported by Mossé[1] was a case in point, for in this case there were found lesions of the sympathetic and microscopic lesions of the adrenals; although I have already explained that I do not believe that the lesion in the suprarenals had a causative relation to the pigmentation. So also the presence, as in our case, of Basedow's disease is an interesting feature pointing to the sympathetic nervous system as the pathogenetic factor in the case.

Glycosuria is frequently an accompaniment of exophthalmic goitre.

Basedow's disease has a very vague pathology. This is hardly the occasion to discuss it; but I may be permitted to express my belief in the neural origin of the disease. Changes have been frequently found in the cervical sympathetic nerves and ganglia, and the medulla oblongata, and such lesions could so well account for the symptoms that I believe they stand in a causal relation to the hyperactivity of the thyroid gland. The theory of Möbius has recently obtained the most general sanction. It consists in its several steps of a lesion causing irritation of the sympathetic or paralysis of the cerebro-spinal nerve supply of the thyroid, and, as a result, increased activity on the part of the thyroid gland. As a sequence of this, an increased amount of the thyroid secretion is poured into the blood. The effects of this are the tachycardia, the prominent eyeballs, the nervousness, and all the other symptoms of exophthalmic goitre. I cannot refrain here from referring to an admirable clinical study by Dr. William H. Thomson of a series of cases having all of the cardiac nervous symptoms of Graves' disease, without the exophthalmos and goitre. He ascribes the pathology to an over-stimulation of the thyroid by a toxæmia of gastro-intestinal origin.[2]

The presence of Basedow's disease in our case, as I have already said, would point to the cervical sympathetic as the lesion which has involved the abdominal sympathetic either by direct extension through the ganglionic connection or indirectly by an affection of the medullary centre presiding over glycosuria, with descending degeneration of the sympathetic and cerebro-spinal tracts which supply the liver and pancreas. The literature upon the combination of diabetes and Basedow's disease is so prolific that we are to be pardoned if we consider the simultaneous occurrence of the two affections as more than an accident. Some of the most recent cases reported are those of Bettman,[3] Grube,[4] Hannemann,[5] and many others. Lepine[6] col-

[6] "Diabète et son traitement," Paris, 1899.

lates a number of cases of the two affections in the same family. In many of these cases, as in ours, the Basedow preceded the diabetes by several years.

All of such occurrences are aids in the localization of the lesion causing the diabetes in the nerve tracts connecting the liver and pancreas with the nerve centres. Further investigations and autopsies will give additional points for localization; a knowledge of the pathological character of the lesions will yield indications for treatment on a rational basis. Syphilitic disease of the viscera or sympathetic causing diabetes, for instance, requires specific treatment, and a successful cure in such a case does not indicate that specific treatment is applicable to all diabetics, and so on. Again, I repeat, localization of the lesion in diabetes and recognition of its pathological character is the plea which I advocate, and I have presented this case partly from its intrinsic interest as an example of a rare clinical condition, and partly because it represents a good illustration of the methods to be adopted in determining the pathogenetic cause of a given case of diabetes.

## THE EARLY DIAGNOSIS OF TUBERCULOUS JOINT DISEASE.

By LEONARD W. ELY, M.D.,

ATTENDING SURGEON, RANDALL'S ISLAND HOSPITALS.

The diagnosis of advanced tuberculous disease of joints is a simple matter. The discharging sinus, the distorted and shrunken limb, the ankylosis, and perhaps the visceral complications present a picture easily understood by the least skilful. The early diagnosis, when the disease is still curable and the return to function still possible, is somewhat more difficult, but really of more importance. In the early stages the disease is seen by the general practitioner or by the general surgeon, and he should be able to make the diagnosis correctly.

Perhaps in no class of disease does the axiom of the old English surgeon so well apply, that the eye should be used first and most and the hands last and least. The hands ordinarily should be used only to help the eye to bring out, as it were, the symptoms for the eye to interpret. Here the general surgeon errs more often than the general practitioner. He has been taught to educate his hands, to cultivate the "tactus eruditus," as he is wont to call it, and his first motion is to put his hand on the offending part. Of course he covers up what he should leave uncovered, and blocks his own way.

In the first place, for the diagnosis a history is needed, and a good one will often point clearly at the result later obtained with certainty. In a large percentage of cases, especially in young children (and with these our subject in the great majority of cases deals), an infectious disease will have shortly preceded the symptoms, and of these the principal ones will be measles, whooping-cough, and scarlet fever, and somewhat in the order named. Often a family history of tuberculosis will be obtained,[1] but whether more often than in any other disease is a question. Next will come the history of the present disease. A few cases come to the physician with deformity and without subjective symptoms, as far as he can ascertain. When deformity sufficient for recognition by the parents attracts attention, the diagnosis by the physician should be a simple matter. These cases will not be discussed here; their proper place will be in the discussion of the various deformities of special regions.

The first characteristic of the symptoms which strikes one forcibly is their gradual development. Often the time of first occurrence cannot be fixed. Next, they are essentially chronic. Next, though sometimes with slight ameliorations, they gradually grow more severe. If some indifferent mode of treatment is adopted, and the patient is seen again at the end of a week or so, he will at least be no better, and at the end of two or three weeks he will be worse than when first seen.

Usually a history of trauma will be given. It is of little use, except for the purpose of excluding fracture or dislocation, for closer questioning brings out that the injury was sustained at a time from a year previous up to the time when the symptoms actually began. When the child limps or is stiff in its movements, the parental mind does not rest until it has remembered a fall or a blow, perhaps not even known to affect the region under consideration. In other words, the symptoms are separated by a distinct interval of time from the trauma, herein differing from contusions, fractures, and dislocations.

Pain and stiffness are two important symptoms. The pain is not exactly located; the patient does not press a finger down on a certain spot, but usually passes it over a region. It is worse on motion and is apt to come in paroxysms at night, when the muscles holding the joint quiet are relaxed. The "night cries" are notorious. The child cries out, and may be asleep by the time the parent reaches him. The stiffness in the morning is also well known.

The general condition of the patient is now to be noted, and then he is to be stripped. This rule knows no exception in children or in men. In women it should be modified but slightly. Next the attitude should be observed, and then the presence or absence of deformity or of change in contour. Here the first difficulty may be encountered by the unpractised eye in recognizing the departure from the normal; but this difficulty exists only in the trunk. In the limbs a guide is present in the limb of the opposite side.

Next, muscular spasm is to be looked for, and this will manifest itself, besides the visible spasm, by limitation of motion in the joint. Here again the same difficulty mentioned above is met, but here again it disappears in the limbs and remains only in the trunk. The joint of the well side is first put through all of its motions—flexion, extension, abduction, adduction, rotation—and the motions of the affected side are compared with these. Any attempt to force the range of motion in a diseased joint will cause pain. In order to elicit this pain the practice of striking the child on the top of the head or soles of the feet, of making him jump from a chair, is quite unnecessary. Sensitiveness to pressure need not be expected; hence the inutility of prodding the part with the fingers. It is no symptom of early tuberculous disease; nor is increase of temperature, except sometimes in joints which are near the surface, *e.g.*, the ankle.

The joints most liable to tuberculous disease in their order of frequency of attack are: 1st, spine; 2d, hip; 3d, knee; 4th, ankle; 5th, elbow; 6th and 7th, wrist and shoulder.[1] Affections of other joints are rare—so rare that they may be omitted from this discussion.[2]

[1] The statements in this paper are based upon four hundred and fifty-three cases of tuberculous joint disease observed at the Vanderbilt Clinic between January 1, 1895, and January 1, 1899. Of these cases a positive family history of tuberculosis was obtained in sixty-eight, a negative in three hundred and nine, and in seventy-six the disease is not mentioned. For convenience, when two or more joints are affected each joint has been counted as a case.

[1] The 453 cases quoted above showed the following distribution: spine 210, hip 155, knee 51, ankle 24, elbow 6, wrist 3, shoulder 4

[2] Sacro-iliac disease, for instance, of which we hear so often, is really very rare. But one case appears on the records of the Vanderbilt Clinic for four years.

A convenient classification will be: joints of the (1) lower extremity, (2) spine, (3) upper extremity.

1. **Joints of the Lower Extremity.**—The first and usually the most prominent symptom is the limp—a limp, in accordance with what has been said above, persisting and gradually growing worse. Next comes pain. In hip-joint disease this pain is felt in the groin, thigh, hip, or knee; in disease of the knee it is felt about the knee; and in disease of the ankle, about the ankle. A feeling of stiffness is often present and is hard exactly to locate. It exhibits usually the morning aggravation.

The examination should be begun by observing the patient's gait, and he should then be placed upon his back on a table, the two limbs compared, and any difference in contour or in attitude noted.

In hip-joint disease the attitude of the affected limb will almost invariably be changed. Flexion will be present, and usually abduction or adduction. External or internal rotation is also frequent. The examiner must bear in mind that no one attitude is characteristic of this disease, as it is, for instance, of dislocation. The length of the limb will not be materially affected, measuring from anterior superior spine to internal malleolus, but the tape will show a diminution in girth of thigh and calf; in other words, slight muscular atrophy. This diminution will amount ordinarily to a half-inch or an inch. Spasm will be present in the muscles moving the joint, and also limitation of motion in all directions. Flexion may be measured in the usual method, flexing the knee at the same time (to relax hamstrings) and holding the other knee down on the table, or more nicely by gently flexing the thigh and watching the anterior superior spine. With a normal hip the anterior superior spine remains stationary until the thigh is in contact with the trunk, while, with a diseased joint, hardly does the thigh leave the table before the anterior superior spine begins to move, showing that the pelvis is moving, and that therefore there is a limitation of motion between it and the femur.

The range of abduction and adduction is observed best with the thigh and knee flexed at a right angle.

The amount of extension possible may be ascertained by bringing the child to the edge of the table, with the lower extremities hanging over, and noting which hangs lower. Or the child may be turned on his face and one hand placed on his buttocks to hold the pelvis on the table. Let the operator then grasp the ankle with his other hand and, having flexed the knee, attempt to super-extend the thigh. This will be found impossible if the hip joint is diseased.

There should be but two sources of doubt in a diagnosis, namely, contusion and bending of the neck of the femur. The symptoms of a contusion follow immediately an injury and disappear in a few days upon the application of an indifferent mode of treatment, such as a liniment or a spica bandage. Bending of the neck of the femur is essentially a disease of adolescence, is rare, is marked by shortening of an inch or so, and is accompanied by limitation of abduction only. The trochanter may be felt above Nélaton's line.

The knee. The attitude in tuberculosis of this joint is semi-flexion. Usually slight swelling is present and should always be sought for with a tape measure. Both flexion and extension are limited. The well-known backward dislocation is distinctly a symptom of the later stages, and will not be found early in the course of the disease. Atrophy of the thigh and leg is an early symptom, and this with the limitation of motion and the chronic course renders a diagnosis from ordinary synovitis easy. Besides, in tuberculosis the swelling is apt to be doughy.

In disease of the ankle or tarsus the foot will be abducted. When the ankle is affected, the foot will usually be in equinus; when the tarsus is diseased, in calcaneus. The temperature will usually be raised, and atrophy of the calf and limitation of motion will be present.

2. **The Spine.**—An early diagnosis is here often difficult, sometimes impossible until deformity has taken place, but really more important than in any other region, because the deformity, when once present, can never be removed. The guide possessed in joint disease in a limb, namely, the sound joint of the other side, is here of course absent.

It is necessary, in the first place, to bear in mind that, with the exception of a feeling of stiffness, the subjective symptoms will usually not be referred to the spine. They are caused by irritation of the anterior branches of the spinal nerves, and are referred to the regions of distribution of those nerves; hence pain in the chest, belly, or thighs, stiff neck, grunting respiration, etc., are apt to be the first causes of complaint.

The patient should first be viewed in the erect posture and his attitude carefully noted; whether flexion of the trunk is present, or super-extension, whether he supports himself by his hands on the table or on his knees, or whether his shoulders look abnormally square, whether his head is thrown forward or backward, and whether deformity in the spine itself is present—all these should be observed closely. In some cases this last will be the first thing to draw the attention of the parents to the child's ailment. The synonym of the disease, "angular curvature," furnishes a good description of the deformity, and when present in marked degree it can hardly be mistaken. It is a "knuckle," a "bone sticking out," as the parents describe it. In its earlier stages it is not so well marked nor so characteristic; it is then not an angular projection, but an irregularity in outline, a change of contour.

Muscular spasm will cause stiff neck, rigid, square shoulders, difficulty in stooping, super-extension of the trunk, etc., according to the region affected. To demonstrate it in disease of the middle and lower spine, the patient should be laid flat on his face with his arms by his side. His feet should be then lifted in the air. With a diseased spine the back muscles will be seen to spring into prominence in tight contraction, and the spine in the region of the disease to be rigid. In cervical disease the spasm may be elicited by movement of the head.

No results can be obtained by poking the spinous processes to find tender or painful spots. Cutaneous sensitiveness does not exist in tuberculosis of the spine.

A change of contour is present in rotary lateral curvature, but here the curve is from side to side, while in tuberculosis any lateral curve is slight and comes on at a late stage. Spasm of the back muscles is absent in rotary lateral curvature, and any pain will be more in the nature of a tired feeling. Again, in the latter affection the apex of the curve appears to be along the ribs, not on the spine itself.

Round shoulders or round back possesses the antero-posterior curvature, but the deformity is a curve, not an angle, whereas in tuberculosis of this region (the upper dorsal) the deformity is always angular from the start. In round shoulders muscular spasm is absent also.

Rachitic curvature will be accompanied by the other signs of rachitis and not by muscular spasm, and will affect the entire spine with a long, gradual convexity.

Ordinary wry neck can be recognized by its acute onset, its rheumatic or tonsillar history, and by its tendency to affect a single muscle, especially the sterno-mastoid. Caries affects all the muscles in the vicinity of the disease. In a few cases the subsequent course alone will make a positive diagnosis possible.

3. **The Upper Extremity.**—The elbow. The diagnosis here is usually simple. Muscular spasm and limitation of motion are early symptoms, and atrophy of the arm and forearm is present. The joint is swollen and is held in semi-flexion and semi-pronation. Rheumatism is differentiated by its acute onset and its tendency to affect several joints.

What has been said of the elbow applies to the wrist, except that in disease of the wrist the hand has no characteristic posture, and the atrophy of the arm would be slight.

In disease of the shoulder joint the usual symptoms of tuberculous disease are present. One disease resembles it, the so-called rheumatoid arthritis, but this is essentially a disease of later life, and is apt to be accompanied by a grating in the joint.

In conclusion, let it be said that, after thorough examination of the case, if any doubt remains rest and a liniment should be prescribed, a positive diagnosis should be withheld, and the case kept under observation for two or three weeks. A diagnosis of "growing pains" may be disastrous, and nothing is lost by a short delay if the child is kept quiet.

## THE EFFECT OF CERTAIN OCCUPATIONS ON THE PHARYNX.

By SEYMOUR OPPENHEIMER, M.D.,

NEW YORK,

LARYNGOLOGIST TO BELLEVUE HOSPITAL, OUTDOOR POOR DEPARTMENT; LARYNGOLOGIST TO UNIVERSITY MEDICAL COLLEGE DISPENSARY; SENIOR ASSISTANT TO THE CHAIR OF LARYNGOLOGY, UNIVERSITY MEDICAL COLLEGE.

THE deleterious effect supposedly exerted on the mucous membrane of the upper respiratory tract by the occupation of the individual is well exemplified by the granular pharyngitis and congested larynx of public speakers. Not only do these suffer from catarrhal affections of the mucous membrane, but, as we shall see later on, the various forms of acute and chronic inflammation of the pharynx can be directly traced to the occupation in many instances. As certain trades cause or predispose to catarrhal inflammations of the mucosa of the entire respiratory tract, we must study not only the pharynx, but also the nasal tissues; but it is here desired to lay special stress on the changes observed in the pharynx in the series of fifty cases forming the basis of this paper. The following case will illustrate the so-called occupation pharyngitis:

Mrs. G. K——, aged thirty-two years, at present a laundress by occupation. She had always been in good health and had no trouble with her nose or throat, until four years ago, when, on account of reduced circumstances, she sought employment as a "bleacher" in a laundry. Within three or four months her general health began to fail and she was troubled with frequent attacks of sore throat. During the periods in which her throat was not actually inflamed there were constant expectoration and post-nasal dropping. Examination of the pharynx showed the mucosa to be relaxed and congested, with superadded inflammation, while the nasal tissues were markedly congested and there was considerable stenosis from the turbinal swelling. The usual treatment proved of little value until she changed her occupation, when the affection no longer caused any annoyance.

Considerable variance exists among physicians as to the effect of heat, cold, and humidity upon the pharyngeal mucosa, and further scientific experimentation is needed before a definite answer to this question can be elucidated. Gradual changes of temperature, extending over the thermometric scale from freezing-point to 96° F., have practically no deleterious influence on the pharynx, provided respiration be nasal in character. The cavernous tissue of the nares adjusting itself to the altered thermometric conditions and from the increased blood supply to this region, additional heat is provided to warm the low temperature air, so that when it reaches the pharynx no chilling or irritating effects are appreciable; the contrary taking place when the temperature reaches the higher portion of the scale. Excessive heat, however, apparently produces morbid changes in the lymphoid tissues of the pharynx, but this, as shown by the dry throat of those remaining for prolonged periods in overheated rooms, depends not entirely on the degree of temperature, but to a great extent on the presence of dust, irritating particles, and the dryness of the atmosphere. Excessive cold, by chilling the surface of the body, may produce increased activity of the pharyngeal mucous membrane, even going on to acute inflammation, and if the individual be exposed for variable periods of time, chronic changes ultimately take place from repeated acute attacks of angina.

Of far more importance than continued heat or cold to the welfare of the mucous membrane is sudden change in temperature; on a large scale this is well shown in countries where temperature extremes are prevalent, especially in the eastern portion of this country. As a general rule it may be said that where temperature changes are marked, catarrhal conditions are prevalent; this applies also to certain occupations; the worker in cold-storage warehouses, coming from a room of very low temperature out into the hot air of midsummer, is a frequent sufferer from pharyngeal affections. The degree of humidity is also a factor of vast importance, and sudden changes in the amount of atmospheric moisture are productive of a greater proportion of cases of pharyngitis than is either heat or cold. In this connection must also be taken into consideration the presence of fine dust or irritating particles in the respired air. These deleterious substances may be either chemical, as in dyeing yarns, etc., or bacterial, as in the air of the overcrowded and poorly ventilated sweat-shop.

The constant inhalation of smoke is a frequent cause of "industrial" pharyngitis, as is also the breathing of acid fumes, as exemplified in the following case:

J. R——, male, aged thirty-nine years, tinsmith by trade. He had no previous trouble with his throat until about one year ago, when he commenced to work at soldering sheets of metal. A mixture of several acids was used in this process, and the fumes arising when heat was applied were a source of constant irritation. On examination, the pharynx was seen to be moderately sclerosed, with the presence of superadded inflammation. The patient stated that his throat had been constantly sore since he assumed this occupation and was getting worse; it was also more painful at night, after he had been at work all day, than in the morning. As in the preceding case little result was obtained from the treatment until he ceased work for two weeks, when the acute inflammation disappeared and he had no trouble until he again returned to work, when the throat symptoms speedily returned.

The question at this point naturally arises as to why certain occupations cause or predispose to pharyngeal affections. The solution of the query is most complex, and to obtain a fairly accurate answer would require extended study of series of cases occurring in persons engaged in various pursuits. In the case just cited the etiological factor is readily appreciable, and so it is in many similar instances, but in the weaver and allied trades numerous factors in the etiological complex must be taken into consideration in addition to those already mentioned, the principal factors that influence the individual case being the age, both as related to the appearance of the pharyngeal trouble

and the period at which the individual first entered his occupation; environment, both at home and in the factory; while the existence of nasal or general affections detrimental to the well-being of the worker must also be considered.

Of the fifty cases studied, twenty-nine were male and twenty-one female. The sexes therefore were about equally involved and apparently bore no relation to the subject. The cases were not selected, but tabulated as they were seen in consecutive order, and the following points were obtained by subjective and objective examination from each: sex, age, occupation, effect of occupation on the pharynx, presence of noticeable throat "catarrh" before assuming present occupation, and the variety of pharyngitis present. The youngest patient was thirteen years old, while the oldest was seventy; there were nineteen under twenty years of age and thirty-one who had passed this period. It was found that the age of the patient in itself bore no relation to the development of catarrhal affections of the pharyngeal mucosa, but of considerable interest was the fact strongly made evident, that the large majority of the patients stated that the daily labor at the loom or similar trade was vastly more detrimental to those under twenty years of age than to those who assumed such occupations for the first time when older in years. In other words, all things being equal, the younger the mill worker the more rapidly would pharyngeal disorders appear; or, provided the individual already had pharyngitis, it would become worse in the youth at a much earlier period than it would in the adult.

As the cases were not selected, there were of necessity members of various trades, which at first appearance, from the limited number of cases, would apparently vitiate any conclusions that might be made; but this was found not to be the case, as the elementary etiological factors were so marked that the distinct occupations could readily be placed under separate groupings and would indicate that but a few definite factors are instrumental in the production of morbid changes of this portion of the respiratory mucosa, as we shall see later on. Of the separate occupations there were weavers or assistants 29, tinsmith 1, hat manufacturers 11, tailor 1, baker 1, dyers 3, fireman 1, carpenter 1, dressmaker 1, and laundress 1, making a total of 50 cases. As the hygienic surroundings and atmospheric conditions of a number of these occupations were practically identical, they can readily be grouped under two headings: first, occupations characterized principally by temperature elevation and the presence of an excessive amount of fibres and dust in the atmosphere, as in the weavers, a portion of the hat manufacturers, tailor, baker, fireman, carpenter, and dressmaker, or thirty-nine of the total number of cases; secondly, those in which the occupation was characterized by the presence of an excessive amount of deleterious chemical agents (acid fumes) in the respired air; this class was composed of eleven patients as follows: hatters, tinsmith, laundress, and dyers.

The relation borne by the distinctive occupation as a causative factor in the production of the morbid changes of the pharynx could be solved only by the history of the patient, and especially by obtaining relief from the throat symptoms by leaving the trade supposedly acting as a cause. This latter, however, is practically impossible, and we must depend upon the statements of the patient in answer to this question. In every case the individual claimed that the throat trouble resulted from the occupation, and in the majority this can be assumed to be true, as this class rarely change their occupation; and further evidence of considerable weight on this point is, that when the mills are shut down for several weeks at a time, and the worker leads more or less outdoor life during this non-working period, the pharyngeal symptoms respond much more rapidly to treatment, and often when no medication is used whatsoever the attention of the individual is attracted to the improved condition of the throat. This, however, rapidly returns to its former condition within a few weeks after resumption of work.

Dependent also upon the history as related by the patient is the answer made to the question as to the presence of noticeable throat symptoms indicative of the various forms of catarrhal affections before the individual assumed the occupation directly relating to the present study, in all the cases under twenty years of age; and this arbitrary age period was selected for the reason that no previous throat symptoms had been experienced except those resulting from occasional attacks of coryza, such as is common to all individuals irrespective of occupation. The answers obtained from the patients over this age, and they were in the majority, showed that the greater part had no pharyngeal disorders previously, while a small number were troubled with previous pharyngitis, but it became markedly aggravated while at their occupation. Examination of the pharynx revealed three so-called forms of pharyngitis to be present: in thirteen there was inflammation, without other pathological changes; in fourteen the mucous membrane was sclerosed, while in the remaining twenty-three there was atrophy of both the mucosa proper and the glandular structures.

Without burdening this paper with further details, it was ascertained from the nature of the occupation, and especially the duration of time the individual had worked at the same trade, that the pathological alterations were, with but few exceptions, directly dependent upon the nature and amount of foreign material in the respired air of the workroom. In the thirteen cases of what we may speak of paradoxically as acute inflammation of long duration the patients breathed an atmosphere more or less constantly surcharged with chemical vapors, during a considerable portion of the day. This class comprised a laundress, whose occupation consisted in bleaching soiled clothing, with a chemical compound of unknown formula; in six cases (hat manufacturers) the workers were constantly associated with various chemicals and especially mercury, used in preparing furs for felt hats; two mill hands were engaged in bleaching, three in dyeing yarns, and one tinsmith, whose case has been given above as an illustration *in extenso*.

Chronic follicular pharyngitis, granular sore throat, or, as it is more frequently called, sclerotic pharyngitis, was represented by one dressmaker, ten weavers, one fireman, and two felt-hat finishers, a total of fourteen cases; all of whose occupations were similar, inasmuch as the pharynx was subjected to constant irritation by minute particles of cloth, ashes, etc., in the respired atmosphere. The presence of atrophic changes of the pharyngeal tissues resulted from long-continued occupation in an atmosphere containing practically the same deleterious substances as that breathed in the sclerotic cases. Of these there were three hatters, seventeen weavers, one carpenter, one baker, and one tailor.

The symptoms of the various morbid changes in the pharynx were the same as those commonly observed irrespective of occupation, and need no further mention here. All cases under the respective groups of sclerosis and atrophy were, of course, not pure cases of these pathological changes. Frequently sclerosis and atrophy were present at the same time, but, depending upon the duration of the throat affection, one was more marked than the other, and was accordingly classified from a point of the greatest pathological alteration predominating. It was also evident that sclerosis and atrophy of the pharyngeal and adjacent portions of the upper respiratory tract were simply

changes in the same chain of events, the smooth, glazed surface, to which dry mucus adhered in small amounts, being the last stage of the morbid process, while subacute congestion and the various grades of sclerosis represented earlier stages of the same affection.

Two factors not as yet considered must here be mentioned, the first being the influence exerted on chronic processes by repeated attacks of acute pharyngeal inflammation, and the second being the intimate relationship existing between the nasal chambers and pharynx, both in health and disease. As is well known, repeated attacks of congestion, at frequent intervals, ultimately lead to chronic changes in the tissues so subjected. This is essentially so of the parts under discussion, and must be given a place, although secondary, when balancing the etiological factors in the class of cases with which we are here concerned. Intimately connected with this factor is the relation existing between the nasal cavities and the pharynx. It is unnecessary to enter fully into the physiology of the turbinal tissue; suffice it to say that, unless the nasal chambers are approximately normal in function, the other portions of the respiratory tract, and especially the pharynx, must invariably participate in the morbid process, and as a result, in the majority of occupations here named and the environment of the people so employed, both nasal and pharyngeal tissues must suffer. In the worker at the loom or allied trades, turbinal swelling and nasal obstruction are of most frequent occurrence, both as a result of the irritating particles in the respired air and from temperature changes, so that mouth-breathing with all its disastrous pharyngeal and other consequences follows as a matter of course. This is well shown even in the ordinary furnace-heated dwelling-house, the extreme dryness of the air causing irritation and swelling of the erectile tissues with occlusion of the nares. Mouth breathing, as before remarked, then ensues, and, as a result of the mucus drying and closely adhering to the pharyngeal walls, normal secretion is perverted or markedly diminished, and atrophic changes supervene. At first the nasal obstruction is but temporary, but as a result of the uncomfortable sensation caused by the adhering pharyngeal mucus, mouth breathing is still further indulged in, even when the nares are free.

As the ultimate object of all such studies is the prophylaxis and treatment of these morbid conditions, a few words on this aspect will not be out of place. Treatment may be dismissed from any further consideration, as it bears no relation to the occupation as a factor, and the therapeutic means used will depend upon the choice of the laryngologist.

Prophylactic measures here, as elsewhere, are very important, and much has already been done toward elevating the hygienic standard of the mill worker, by improving his daily surroundings in the way of better ventilation, the elimination or reduction of the excessive dust in the respired air, and increasing the age limit at which the youth is permitted to enter these occupations. As regards the prevention of catarrhal affections of the upper respiratory tract, daily washing with an inexpensive alkaline antiseptic solution will be of much value; this should be done morning and evening, and during the working hours a few drops of any of the refined petrolatum oils should be placed in each nostril. This procedure has been followed out in a number of cases among weavers, etc., and most gratifying results have been obtained.

From the small number of cases here presented, no specific conclusions as applied to occupation can be drawn, but the following suggestions are equally true in a larger sense, as indicating broader lines than the number of cases here studied warrants. We may suggest then that—

1. The pharyngeal mucosa of the mill hand under twenty years of age is more susceptible to unfavorable influences than is that of the individual over this age.

2. The inhalation of dust, fibres, and chemical agents are the factors of most importance.

3. The majority of industrial workers are affected with pharyngeal disorders, dependent to a certain extent upon their occupation.

4. In those already affected with pharyngitis before assuming these occupations, the morbid changes are augmented by the work.

5. The primary pharyngeal changes are those of acute congestion and inflammation. Chronic changes are the ultimate result.

6. The pharyngitis produced in part or whole by the occupation does not differ in any respect from the ordinary forms.

7. Provided the nasal chambers be in approximately normal condition, pharyngeal affections are much less liable to occur than otherwise.

8. Hygienic measures applied to the environment of the worker are of vast benefit as regards the improvement of his general condition and therefore of the upper respiratory tract.

9. That local care, as has been outlined, will be productive of much good.

706 Madison Avenue.

## Progress of Medical Science.

**Diphtheria Poison as It Affects the Heart.**—After a series of experiments on animals Dr. Rolly (*Arch. fur Path. und Pharmak.*, Bd. xlii., 1899) finds that the fall in blood pressure is due to paralysis of the vasomotor centre, and to paralysis of the heart. The action on the heart is direct and independent of the nervous system in warm-blooded animals. There is a more or less distinct period of latency before paralysis occurs. Thus when the poison is injected directly, or when lethal blood is transfused, the action upon the isolated normal heart of a rabbit takes place only after a latent period. If the heart is washed out with normal blood before the symptoms appear, or at the onset of toxic effect, the poisonous action asserts itself just the same. This leads to the opinion that the poison attacks the heart, and appears to be stored up in the heart muscle until its complete action is manifest.

**General Paralysis and Syphilis.**—While it has long been considered that syphilis was responsible for most instances of general paralysis of the insane, few have believed that it was invariably so. In two recent discussions at the British Medical Association and in the Medico-Psychological Association, Dr. Campbell and Dr. Mott arrived at practically the same conclusions, viz., that syphilis is not an indispensable factor. The arguments for relationship as given in the *Medical Times and Hospital Gazette*, October 7th, are: (*a*) that a history of syphilis is obtainable in a large number of the cases—varying from twenty-four per cent. to eighty-six per cent. with different observers; (*b*) that general paralysis is most common in towns where immorality and syphilis are most rife; (*c*) that general paralysis is practically unknown in those parts of the world where syphilis is practically unknown.; (*d*) that most cases of juvenile general paralysis possess syphilitic stigmata (Hutchinsonian teeth, etc.); (*e*) that no case is on record of a general paralytic developing syphilis; (*f*) that a large proportion of general paralytics have spots (revealed post mortem) of syphilitic endarteritis in their cerebral arteries; (*g*) that inactivity of the pupil to light—a symptom which occurs

in about seventy-five per cent. of general paralytics—is now regarded by most neurologists as a sign of past syphilis. The arguments against the relationship are: (*a*) that general paralysis does not respond to mercury and potassium iodide; (*b*) that thorough antisyphilitic treatment at the time of syphilitic infection does not avert general paralysis; (*c*) that general paralysis is an unknown disease among certain well-syphilized races.

**A Case of Severe Crushing of the Abdomen.**—Bardenheuer recalls, in the *Wiener medizinische Blätter* of October 5, 1899, the case of a young man who had been run over. The patient showed all signs of severe shock, and, as his condition was becoming worse, the abdomen was opened and much fluid blood removed. At the same time it was discovered that the posterior parietal layer of the peritoneum on the right side was distended by a collection of pus till it appeared like a cyst. No bleeding point in the abdomen being found, the blood could have entered the abdominal cavity only from a lesion in the peritoneum. Bardenheuer exposed the kidney and discovered a large tear in its upper pole. The kidney was removed as well as the retroperitoneal blood mass. During this procedure, he discovered a tear in the posterior parietal layer of the peritoneum and a star-shaped lesion in the posterior lobe of the liver. The hemorrhage still continuing, Bardenheuer drew out the liver, the organ being deeply lacerated. He applied pressure, and used the Paquelin. The wound was packed with iodoform gauze, and the patient made a good recovery.

**A Case of Gun-shot Wound of the Heart.**—In the *Wiener medizinische Blätter* for October 5, 1899, Bardenheuer reports a case in which the patient was shot through the heart. On account of the acute traumatic anæmia following, Bardenheuer resected the fifth and sixth ribs, from the apex of the heart to the breast bone, and laid bare the pericardium, by which he exposed the opening in the anterior wall of the sac. By means of a clamp which closed the wound, he thought he had stopped the bleeding, thinking he had to deal with one of the rare cases of isolated lesion of the pericardium with profuse hemorrhage. He removed at least two litres of blood from the left pleural cavity. Since the pericardium was closely attached to the heart, and as no more blood collected in the pleural cavity, Bardenheuer believed that the hemorrhage had ceased. He therefore packed the wound. The patient died half an hour later. The necropsy revealed an unsuspected opening in the posterior wall of the pericardium, as well as in the wall of the left ventricle, although the cavity itself had not been entered.

**Treatment of Congenital Stenosis of the Pylorus.**—Dr. Rudolf Neurath, in discussing in the *Centralblatt für Schweizer Aerzte* of October 1, 1899, the treatment of congenital stenosis of the pylorus, says that its prognosis is fairly good. Although the quality of food is not of great importance, nor even a change in diet, nevertheless a methodical diminution of the quantity is often attended by good results, as has been seen in the cases of Hirschsprung, Finkelstein, and Senator. As to medicinal measures, different physicians have made use of Carlsbad salts, belladonna, calomel, and resorcin. Bendix advises clysmata, suppositories, high injections, and massage, for the alleviation of constipation. For vomiting, he washes out the stomach, while for the painful contractions of the stomach he uses poultices and small doses of opium. He also recommends that nourishment shall be given at short intervals. Schwyzer first suggested operative treatment and considered it the only possible method, advising either Loreta's operation or a simple gastro-enterostomy. Meltzer first attempted the surgical treatment, performing a gastro-enterostomy, which was followed by death in thirty hours. Stern in one case performed gastro-enterostomy, which was interrupted by two unfortunate accidents—collapse during narcosis, and almost complete eventration while the operation was continued without narcosis. Six hours after the operation a spontaneous movement of the bowels occurred, but death followed soon after. In spite of this, Stern advises operation for all cases of absolute stenosis of the pylorus which present the symptom complex of absolute obstruction of the bowels. Pfaundeler is much opposed to the surgical treatment of stenosis of the pylorus, and believes in the local application of narcotics, anodynes, warm poultices, protracted baths, and systematic stomach-washings—the last on account of their soothing influence on the stomach wall. The diagnosis of stenosis of the pylorus in later life is far more difficult than in early years. Indeed, a differential diagnosis is scarcely possible, nor is it of great value. The work of Carle and Fantino (*Centralblatt*, i., p. 239) should be recalled. The authors give proof for the hypothesis which holds hyperacidity responsible for spasm of the pylorus, namely, in the closure of the pylorus during the production of hydrochloric acid. Although in the greatest number of cases the spasm is primary, it is undoubtedly increased by hyperacidity. In these cases, of course, operative treatment is not to be considered.

**The Use of Boric Acid and Formalin as Preservatives of Milk.**—As the result of an investigation undertaken for the purpose of determining the harmfulness of boric aid and formalin when used as preservatives of milk, Annett (*Lancet*, November 11, 1899, p. 1282) has found that these chemicals, when so used, are injurious to the health of the consumer, and particularly so to that of young infants. Further, it is easy to conceive that the great mortality rate among infants from diarrhœa in many large towns may be closely connected with the practice, especially during the summer months, of systematically "doctoring" milk by means of the preservatives used by milk purveyors, dairymen, and milkmen.

**Dieting in Pregnancy.**—In contracted pelvis and other conditions in which it is desired to keep down the size of the fœtus, Dr. Bedford Fenwick (*Medical Times and Hospital Gazette*, September 16th) advocates rigid dieting with restriction of starches, sugars, and fluids. The following is an example of the dietary followed: For breakfast, a small cup of tea or coffee, an egg, and two slices of toast. For lunch, any kind of meat, game, or fish, green vegetables, one slice of toast or a dry biscuit, cheese, one wineglassful of wine, milk, or any other fluid, excepting malt liquors. At afternoon tea, a small cupful of tea or coffee, with one slice of bread and butter, or cake. For dinner, the same as for luncheon.

**Anterior Transplantation of the Round Ligaments for Displacements of the Uterus.**—Ferguson (*Journal of the American Medical Association*, November 18, 1899, p. 1275) describes as follows the successive steps in an operation for the correction of uterine displacement: A skin incision, three inches long, is made in the median line, beginning one and a half inches from the symphysis pubis. The linea alba and the anterior sheath of the recti muscles are exposed, and an incision is made on either side through the anterior sheath of the recti. The rectus muscle is retracted outward, and an incision is made into the peritoneal cavity directly behind it through the transversalis fascia and the peritoneum. The round ligament

and a portion of the broad ligament are seized with forceps one inch from their origin, the round ligament and the broad ligament external to the forceps being tied and divided between. The tied distal end of the round ligament is dropped into the peritoneal cavity, and the proximal end is lifted well out of the wound into the peritoneum. The round ligament and its accompanying portion of the broad ligament are attached to the wound in the transversalis fascia and peritoneum. The fibres of the rectus muscle are replaced and the wound is closed in its anterior sheath, with a continuous catgut suture which grasps the cut end of the round ligament. The opposite side is then treated in the same manner. Then the skin incision is closed.

**An Experimental Study of Aspirin.**—This new salicylic-acid preparation, or rather product of a combination of acetic acid with salicylic acid, has been experimentally studied by Floeckinger (*The Medical News*, November 18th). The lethal dose of this acetylsalicylic acid was found to be in guinea-pigs 1.5 gm. per kilo weight. It is given in dose of gr. xv. in alcoholic solution.

**The Nature of Exophthalmic Goitre.**—Robinson, in his study upon the Graves-Basedow disease as a manifestation of hysteria and not purely a neurosis as taught by the followers of Charcot, concludes: Exophthalmic goitre should be ranked as a manifestation of hysteria. The neurosis originates over-active function of the thyroid gland, leading to histological changes. This is indicated by the establishment of thyroid intoxication. The hysteria followed by this intoxication explains all the symptoms, although in some cases the intoxication fails to appear. The treatment should not be surgical in nature, unless a determining cause, such as a fibroma uteri, salpingitis, or other similar pathological lesion, is present.

**Upward Dilatation of the Stomach.**—At a meeting of the Clinical Society of London, Ewart (*Lancet*, November 4, 1899, p. 1233) exhibited two patients presenting upward dilatation of the stomach. The symptoms complained of were an ill-defined feeling of malaise, together with embarrassment of the heart's action and of respiration. The first patient had suffered from so much discomfort for two and a half years that he was unable to earn his livelihood. The condition had begun suddenly after a prolonged bicycle ride with consequent exhaustion. The second patient also was unable to work, but in him much exertion brought on severe anginoid seizures. In this case the dilatation of the stomach was probably due to unmasticated food, for the teeth were bad. In both cases the precordial region was encroached upon by the gastric resonance, which, in the first case, rose as high as the left nipple. Both patients had improved under respiratory exercises—a line of treatment that was directed to strengthening the diaphragm and the abdominal muscles—and the wearing of an abdominal belt.

**Bacteriuria.**—Dr. August Predöhl (*Münchener medicinische Wochenschrift*, November 7th) says that this condition is more common than is generally supposed. Cases may be divided into acute, subacute, and chronic, or again into very severe, severe, and mild. This classification does not, however, comprise and cover all instances, even though the most severe of the cases was an acute one, the next severe case a subacute, while the cases becoming chronic were for the most part mild. All the patients were women, and it may be reiterated that this condition is frequently observed in the female sex. The onset of the disease is in some instances always about the same, in others quite varied. Common to all is the beginning with burning pain upon urination, which occurs only or mostly upon evacuation of the last few drops; this may reach a point of tenesmus, with dropping of urine and increased desire of urination even to incontinence. Varied were the bladder pains, pains in the region of one or both kidneys, which were designated as backache by the patients, but which upon close questioning and examination could be localized to the renal region. This condition suddenly attacks individuals whose previous health has been good and occurs without any definite etiological basis. Exposure to cold, long retention of urine, and habitual constipation play some part. The urine is always cloudy, does not clear up when heated, contains no albumin, is acid in reaction, and shows nothing definite with the ordinary chemical examinations. The urine looks like a weak soap water; indeed, it may be compared to a hazy bouillon culture. In some instances it has a very pronounced and disagreeable smell; most generally, however, there is no bad odor. In some cases the patients seek medical aid only on account of the bad-smelling urine. If this urine is centrifuged or left to sediment, the deposit is found to be made up of micro-organisms, which prove to be the bacterium coli in all instances. Pure cultures were also grown from the sediment. Microscopical examination of the urine shows only epithelia in addition to the above; in other words, the absence of any bladder or kidney disease. In some cases this condition is followed by disease of these organs or the abdominal viscera. Many instances are looked upon as a mild cystitis and intestinal colic. The patients are generally slender, pale, moderately nourished individuals who do not feel sick; in some cases, at the time of the attack, the patients feel very sick. The term bacteriuria is used only for such cases in which, in healthy individuals without any clinical evidence of inflammatory processes in the genito-urinary tract, and without definite cause, micro-organisms are found in the freshly evacuated urine and give rise to symptoms of disease. This, therefore, does not include those instances in which bacteriuria is secondary, that is, those in which an inflammatory or diseased area previously existed, thus enabling the bacilli coli to gain entrance into the urine. On the other hand, bacteriuria includes such cases in which, as the result of the condition, cystitis, pyelitis, nephritis, or disease of the genitals occurs. Bacteriuria pure and simple often disappears without any treatment; treatment is purely symptomatic. Salol has given the best results. Analgesics have no effect; iron is very useful. Warm baths are indicated; opiates are sometimes absolutely necessary. In some cases an ice-bag over the bladder region gives excellent results. The bowels must be freely evacuated. There is no specific drug for this condition. Letzerich recommends benzoate of sodium. The prognosis is always doubtful. While in some instances bacteriuria appears to be harmless, still it is always very difficult to get rid of and render the urine absolutely free from bacteria. The disease, therefore, is always to be looked upon as serious.

**Indication for Surgical Operations.**—Dr. R. Gersung (*Wiener medizinische Blätter*, October 26th) says that diagnosis is the most important basis of our therapy, which after all is the main aim of the physician. In surgical operations we must consider the prognosis with and without operation; furthermore, the prognosis of the operation itself. For the prognosis in purely expective treatment we can fall back on long years of experience, whereas the operative therapy has undergone numerous changes in a relatively short period of time. Thus, for example, the operation of ovariotomy was formerly considered fatal, and the only intervention permissible in ovarian cysts was puncture; later

ovarial operations became more frequent as soon as it was learned that many tumors which were benign at the beginning became malignant. The same condition is seen in carcinoma, which, whenever possible, is to-day radically operated upon. Often the operation must be undertaken without a previous positive diagnosis (exploratory incision and operation); in these instances symptoms compelling an operation arise, *e.g.*, intestinal obstruction. Formerly the intestinal puncture was performed as a palliative measure; nowadays enterostomy is performed upon the same basis, *e.g.*, in inoperable intestinal carcinoma or when a major operation cannot be withstood. In the indications for operative intervention in ileus the surgeons have gained much; while in former times they received only such cases as were beyond the control of medication, to-day operative therapy holds first place. In the indications for perityphlitis, three groups must be differentiated: the acute attack, the recurrent, and the chronic catarrhal form. In the first, operation is indicated; the difficulty, however, is to recognize these cases and to operate at the proper time. The indications for operation are: continuous fever for four or five days, the presence of an abscess, duration of the attack for more than twelve days. In recurrent perityphlitis the operation has for its object the prevention of future attacks. In the chronic catarrhal form the object of the operation is to render the patient capable of performing his labors and enjoying life. In prophylactic operations, the chances of the occurrence of a dangerous complication must be weighed against the danger of the operation, *e.g.*, in a non-incarcerated hernia for which relief is sought. Among contraindications a chronic cough may be mentioned. The term radical operation is at present not a very precise one. There are radical operations in which all of the diseased area is not removed, *e.g.*, in tuberculosis. Palliative operations are performed for inoperable intestinal carcinomata (enterostomy), ulcerated mammary carcinomata, furthermore for the patient's peace of mind and to give him the hope of a cure. Suggestive operations are of little value, their effects proving illusionary later on. As regards contraindication to operation, the times have changed. To-day we operate in diabetes and pregnancy, and even give anæsthesia in uncompensated cardiac lesions; in the latter cases the danger lies not in the valvular lesion, but in the degeneration of the heart muscle. In deciding whether to operate or not, the personnel of the surgeon plays an important rôle.

**Subclavian Arterial and Venous Murmurs.**—Dr. Albert Abrams (*Medical and Surgical Monitor*, October 15th) concludes as follows: (1) The subclavian arterial murmur is an independent (autochthonous) and rarely a transmitted murmur. (2) Its point of maximum intensity is the fossa of Mohrenheim, with feeble tendency to propagation. (3) It is heard most often on the left side, less frequently on both sides, and least frequently on the right side. In order of frequency it is heard at the height of inspiration, at the end of expiration, and after momentary suspension of respiration. (4) It is usually a succession of murmurs uniform in character and intensified by certain manœuvres, notably deep inspiration, forced expiration, suspension of respiration, and voluntary stretching of the neck. (5) One of its chief characteristics is its momentary duration, disappearing usually after a few deep inspirations. (6) Its dependence on the phases of respiration distinguishes it from all transmitted murmurs. (7) It may be present at one and absent at a subsequent examination, and neither its character nor its duration is ever uniform from one examination to another. (8) The position of the patient may influence its genesis, but this is never sufficiently uniform to be of practical value. (9) A phthisical lung is not specially propitious to its occurrence, as it is found nearly as often in healthy as in phthisical persons. (10) It was present in thirty-six per cent. of all healthy persons examined, advantage being taken in this enumeration of re-examinations and those propitious factors which determine its occurrence, viz., respiration and decubitus. (11) The venous subclavian murmur was heard only in six individuals with a preponderance of its occurrence on the right side. (12) The arterial subclavian murmur could be artificially induced on the left side in nearly eighty per cent. of all individuals examined, and on the right side in about sixty-five per cent. of the cases, by a simple manœuvre, viz., raising the arm gradually until it assumes a vertical position, while auscultating the Mohrenheim fossa during the time that the arm is brought to the latter position, the murmur suddenly appearing at some time during the execution of the movement. (13) By the foregoing manœuvre the subclavian venous murmur could be induced on the right side in forty-three per cent. of all persons examined.

**Pathology of Beri-Beri in Infants.**—Miura, of Tokio (*Virchow's Archiv*, 155, p. 316, 1899), although formerly opposing the view that infants could be affected with beri-beri, now adopts the positive side and reports some pathological finding from cases occurring in infants and nurslings. Autopsy findings of four cases showed marked changes in the walls of the heart, there being an hypertrophy of the right ventricle whereby the thickness of the walls became as pronounced as that of the left ventricle. This marked hypertrophy was associated with extreme dilatation. There was in addition an atrophy of the lower extremities associated with widespread anasarca. The clinical histories are not given in detail.

**The Phenylhydrazin Test for the Presence of Sugar in the Urine.**—As the result of an investigation into the utility of the phenylhydrazin test for detecting the presence of sugar in the urine, Coriat (*Boston Medical and Surgical Journal*, November 23, 1899, p. 518) concludes that phenylhydrazin forms with the reducing sugars crystalline chemical compounds, each having an individual and definite morphology. In performing the test albumin need not be removed. It is possible to recognize any of the sugars by their crystalline forms alone with recourse to their melting-points. Substances that interfere with Fehling's or Nylander's reagents do not interfere with this test or form anything that would in any way be misleading. The test is an extremely delicate one, and of undoubted accuracy.

**Mastoid Operation.**—Dr. S. G. Dabney (*Medical Age*, October 10th) concludes: 1. In all operations scrupulous attention must be paid to surgical cleanliness, as the unexpected may happen and some meningeal exposure be found. 2. In periosteal inflammations an incision should be made over the mastoid down to the bone and the bony surface carefully examined. 3. When the mastoid antrum is to be opened, the opening should be just behind the external meatus and just below its superior border. 4. Chisels and mallet are the best instruments for opening the mastoid, followed by curette, sharp spoon, and rongeur forceps. 5. It is best to establish drainage through the mastoid antrum into the tympanum. 6. It is of great importance to examine the process in the direction of its tip, and if need be to open it up thoroughly. 7. The upper part of the wound may be closed with a few stitches; iodoform gauze should be packed into the lower part and well into the bony cavity. The subsequent dressings and irrigation may be determined by the absence of fever and other septic symptoms.

## RACIAL DETERIORATION.

PERHAPS on this subject more ink has been spilt than on any other of the burning sociological questions which our modern civilization has brought into prominence. The exodus of the population from the country to the towns is continuous and increasing yearly. This being so, it follows as a matter of course that the human race will to some extent lose those physical characteristics which distinguish the dwellers in the pure atmosphere of the country, and who still further harden their constitutions by manual labor in the outside air. In fact, the question as to what effectual means can be taken to render the life of the inhabitant of a large city more healthy, and to propagate a race better fitted to cope with the strain of modern existence, is one the importance of which looms up with growing significance day by day. That town life, and especially as spent by the working and poorer classes, is incompatible with good health is too notorious to need emphasis. But several facts that have been brought to the notice of the public recently have again engaged the attention of social reformers and further clinched the argument that the matter should be squarely faced and immediate steps taken to ameliorate the condition of that portion of the population which Mr. Stead has aptly termed "the submerged tenth."

It will doubtless be recollected by our readers that at the time of the outbreak of our war with Spain, and when patriotic citizens were rushing to enlist, a large proportion of these were disqualified by the examining physicians as physically unfit. The same thing is now occurring in Great Britain, and within recent years in that country the standard of would-be army recruits has had to be considerably lowered.

The measures suggested to counteract this evident evil have been various. Among other Utopian and impossible remedies advanced by sociologists is that a large part of the poverty-stricken population of cities should be induced to revert to country life. This plan, however plausible it may look in print, will be found to present insurmountable difficulties and may be dismissed as illusory. What is really required is that the large centres of population should be placed in a satisfactory sanitary condition, and that the homes of the toilers should be made commodious and hygienic. The ill-ventilated rookeries that disgrace towns in all parts of the world should be swept away, and in their stead houses in which human beings can live and breathe, not merely exist, should be erected.

There is unfortunately, however, another and more hopeless class than the workers who must be considered. These are the so-called degenerates. This species may be said to swarm in all large towns. Mr. Arnold White contributed an article to the October number of the *National Review*, entitled the "Cult of Infirmity," in which he inveighed against the lax and ineffective methods of dealing with this description of individual. He said: "Of the London and New York unemployed, at least two out of every five are not only unemployable, but unworthy of help," and further suggested the following drastic means of ridding the community of these pests: "Extirpate them by immuring them for life, not because they are wicked, but because their stock is corrupt." Mr. White declares that the majority of these degenerates are brought to the pass in which they find themselves by their own vicious faults, and quotes the late Sir Andrew Clark as stating that seventy per cent. of the patients under treatment in the London Hospital, Whitechapel, owed their ill health to preventable causes. The article in the *National Review* reviews the situation in these outspoken words: "In our great cities no social stigma attaches to preventable ill health. Parental neglect, premature and reckless marriage, leading to the multiplication of tainted brains and rickety frames, are matters of no importance to practical politicians. Christian charity is invoked to canonize weakness, while preventable weakness is honored under the sacred principle of individual freedom. No law prevents the union of a consumptive swain with his strumous sweetheart; no restriction interferes with the colonization of our towns by diseased aliens; neither Church nor State debars penniless and undersized striplings from undertaking parental responsibilities."

Every word of this statement is true, but, looking at the matter from the standpoint of sound common sense, an absolute cure for the existing state of affairs does not seem to come within the sphere of practical social reform. The evil may be scotched, but not altogether killed, and we shall doubtless have our degenerates and diseased with us so long as the world lasts. In the first place, we take it, something should be done for the deserving poor, and after that scheme has been brought to a more or less successful issue, we might turn our attention to the degenerates. However, this much may be said, that to the person who succeeds in even a slight degree in bettering the condition of our working classes and pauper population is due a greater triumph than is accorded to a victorious general or admiral. Probably the only true and effectual remedy lies in the education of the masses.

**Importing a German Custom.**—Dr. William H. Welch of Baltimore has been teaching in medical schools for twenty-five years, and his former pupils are going to write a book in his honor.

## SURGICAL TREATMENT OF DUODENAL PERFORATION.

Ulceration of the duodenum is dependent upon much the same causes as the similar lesion of the stomach, including vascular, hæmic, circulatory, and secretory alterations, and neurotic states, although burns of the surface of the body are believed to be especially provocative of duodenal ulcer. The lesion may be present in both or in several situations simultaneously, although usually single and far more common in the stomach than in the duodenum. All ages are susceptible, although males appear to be attacked with greater frequency than females, in contradistinction from gastric ulcer. The diagnosis is easy if melæna occurs, with or without hæmatemesis, if the characteristic pain is situated far to the right and, with the vomiting, occurs later. The treatment is based upon the same lines as that of gastric ulcer, including surgical intervention if hemorrhage is frequently repeated or severe, or perforation threatens or occurs. An illustration of the practical application of this principle is afforded by a case recently reported by Johnson (*Annals of Surgery*, November, 1899, p. 634) at a recent meeting of the New York Surgical Society. The patient was a man twenty-seven years old, who was admitted to the hospital at three o'clock in the morning with a history of having been seized four days previously with colicky pain referred to a point above the umbilicus and to the right of the median line. There were no vomiting and no chill. The pain was not severe, but continued during the following two days, and was always referred to the same region. The bowels moved daily, and the man continued at his work. A short time before admission the patient was awakened from sleep by severe abdominal pain, most intense three inches above the umbilicus and a little to the right of the median line, which was followed by a chill lasting half an hour. There was no nausea, but the patient took some mustard and water, which induced free vomiting, the vomited matter consisting of partly digested food and the mustard and water that had just been taken.

On admission the abdomen was not distended, but was moderately tender, with well-marked muscular rigidity throughout. The tenderness was most marked over an area about two inches in diameter, located three inches above the umbilicus, and with its centre one and one-half inches to the right. A small dose of morphine was given hypodermically for the relief of the pain. This was somewhat less severe by morning, but the tenderness was more marked and localized. There was general rigidity of the abdominal wall. The temperature had risen to 101.5° F. A diagnosis was made of acute intra-abdominal inflammation, probably of a suppurative character, upon the right side of the abdomen. The abdomen was opened by an incision two and one-half inches long in the right semilunar line, with its centre at the level of the umbilicus. A considerable quantity of cloudy, bile-stained fluid containing flakes of coagulated lymph escaped. A probable diagnosis of perforated ulcer of the duodenum was now made, but as a matter of precaution the vermiform appendix was sought for and found to be normal. The large and small intestine, the gall bladder, the under surface of the liver, and the anterior wall of the stomach exhibited evidences of acute irritation, and were coated here and there with patches of grayish lymph. Upon the anterior surface of the descending portion of the duodenum, a little to the right and about midway between the junction of the first and second portions at the point where the second passes behind the transverse mesocolon, was a round or oval perforation, large enough to admit a No. 26 French sound, or thereabouts, through which was escaping bile mixed with other intestinal contents. The border of the ulcer was clean cut, not ragged. A pad of gauze was held over the ulcer, and the neighboring portion of the abdomen was thoroughly washed with saline solution. The opening in the duodenum was encircled with a purse-string suture of catgut; the edges of the ulcer were inverted into the intestine, and the suture was tied. The closure was further strengthened, and the tension upon the purse-string relieved, by four Lembert stitches of catgut introduced along a line parallel with the axis of the gut. A considerable quantity of bile-stained, cloudy fluid was found at the bottom of the pelvis, and the intestines were everywhere moderately reddened and coated with disseminated patches of lymph. The edges of the wound were held wide apart, and the entire abdomen was repeatedly flushed with hot saline solution, without evisceration, the fluid being gently stirred about with the hand in the abdomen. The entire cavity was wiped dry with large pads of sterile gauze. A strand of gauze packing was then introduced down to the site of the ulcer, and brought out at the upper angle of the wound. The remainder of the wound was then closed with sutures. The patient did not suffer from shock. He was fed per rectum for forty-eight hours. The superficial wound was dressed on the third day, and appeared to be slightly infected, whereupon the skin-sutures were removed. The deep packing was removed on the fourth day, and was found to be clean. The patient remained in bed four weeks after the operation, and two weeks later appeared to be in perfect health.

Dr. Johnson cited the following statistics: Of 39 cases of duodenal ulcer on record, recovery had occurred in 8; in 20 the ulcer was not recognized; in 2 general peritonitis was thought to exist, in 13 appendicitis, and in 3 intestinal obstruction. Of 19 cases in which the ulcer was found, though not diagnosticated beforehand, recovery occurred in 6. The case reported is the second of recovery in this country, an earlier having been reported by Dr. Taylor, of Richmond, Va.

---

## EOSINOPHILE BRONCHITIS.

The irritation of the bronchial mucous membrane that results in the symptom complex of bronchitis may arise through agencies either introduced from without or generated within the body. Thus the inhalation of noxious gases or of fine particles may be the exciting cause, while the bronchitis that so commonly attends the onset of typhoid fever, and occurs during the course of other infectious diseases, may be considered as of

intrinsic origin. It is not unlikely that under many conditions bacteria may take part in the morbid process, sometimes primarily, at other times secondarily, consequent upon the slight lesions induced by mechanical influences, and at still other times through the agency of toxic substances generated within the body. In addition, it is possible that the metabolic products of abnormal bodily activity may be the responsible factor. Bronchitis must thus be looked upon as a disease of diverse etiology, and the symptoms will vary in detail accordingly. A special variety of the disease has been described by Hoffmann under the name of eosinophile bronchitis, and the conclusions reached from a three years' study of the disorder at the University Poliklinik at Leipsic are detailed by Teichmüller in the *Deutsches Archiv für klinische Medicin*, B. 63, H. 5 u. 6.

Eosinophile catarrh is the name employed to designate a variety of bronchitis in which the sputum is distinguished from that of other varieties of bronchitis by the presence of eosinophile cells in large number. The affection has certain relations with bronchial asthma, of which some of the cases may be considered beginning stages or rudimentary forms. The disease is a catarrhal affection of the bronchi, of rather chronic course, though at times alternating with periods of a completely normal condition. It is characterized especially by the presence of a large number of eosinophile cells in the sputum. Normally, only isolated eosinophile cells are present in the mucous membrane of the bronchi and the trachea. The fundamental origin of the disease is unknown. Among predisposing and determining factors may be mentioned hereditary influences, viz., tuberculosis, alcoholism, syphilis, and neurasthenia, and acquired influences, viz., scrofula, severe rachitis, congenital or hereditary syphilis, pneumonia, traumatic pleurisy, and bronchiectasis. The disorder is more common in males than in females. It is insidious in onset, and gradually progressive in course. It is of rather protracted duration, but its course may be interrupted by long intervals of good health. Under treatment improvement or cure results. Recurrences are, however, readily induced. Respiration is but little changed, and there is but slight difficulty in breathing. In the worst cases the margins of the lungs become emphysematous. In addition to moist râles, principally dry, snoring and wheezing râles may be heard. Cough is rarely absent, and also expectoration. The sputum is transparent, viscid, and loose. Eosinophile cells are present in large number. Spirals and crystals are as a rule absent. Chest pain is usually present. There are besides headache, anorexia, vomiting, constipation, disturbed sleep, and sweating. Elevation of temperature is uncommon. Disturbances of metabolism are usual. The diagnosis depends essentially on the detection of large numbers of eosinophile cells in the sputum. Asthmatic attacks are attended with dyspnœa, the expectoration of a peculiar sputum, and emphysema of the lungs. The prognosis is favorable in uncomplicated cases, less so when deformity of the thorax exists, or previous pneumonia and pleural thickening have been etiological factors. The treatment is essentially hygienic and dietetic, and includes gymnastic exercises, hydriatic measures, potassium iodide in syphilitic cases, cod-liver oil, malt, leguminosæ, and iron and manganese peptonate.

---

## News of the Week.

**An Increase in the Army Medical Staff.**—A bill which has been prepared by Surgeon-General Sternberg will be presented to Congress during its present session. The bill provides for the addition to the corps of four assistant surgeon-generals, with the rank of colonel; ten deputy surgeon-generals, with the rank of lieutenant-colonel; thirty surgeons, with the rank of major, and eighty assistant surgeons, with the rank of first lieutenant, who shall have the rank of captain at the expiration of five years of service. Acting assistant surgeons to the number authorized are to be appointed, subject to the usual examination, for a probationary period of six months, during which they will attend the Army Medical School in Washington, at the end of which time, if their standing is good, they are to be commissioned to fill existing vacancies. This probationary service is waived in the case of candidates who have rendered satisfactory service as acting assistant surgeons or as commissioned medical officers in the volunteer army for a period of six months or more. The vacancies occurring in the grades of major, lieutenant-colonel, and colonel will be filled by seniority promotion.

**The Health Board and the Elevated Road.**—It is reported that the investigation into the alleged unsanitary condition of the cars on the Manhattan Elevated Railroad, which has been begun several times by the board of health, has again been abandoned. Yet to the casual observer there has been no change in the sanitary condition of the cars since the time, a few weeks ago, when officials of the board declared them a menace to the public health.

**The Nicholas Senn Prize.**—Announcement is made of the conditions of competition for the Senn prize medal, a gold medal of suitable design, to be awarded to the writer of the best essay on some surgical subject. The committee of award for this year are Drs. W. L. Rodman, of Philadelphia, A. J. Ochsner, of Chicago, and H. Horace Grant, of Louisville. The following are the conditions: 1. The name of the author of each competing essay shall be enclosed in a sealed envelope bearing a suitable motto or device, the essay itself bearing the same motto or device. The title of the successful essay and the motto or device accompanying it will be read at the meeting at which the award is made, and the corresponding envelope will be then and there opened and the name of the successful author announced. 2. All successful essays become the property of the association. 3. The medal shall be conferred, and honorable mention made of the two other essays considered worthy of this distinction, at a general meeting of the association. 4. The competition is to be confined to those who at the time of entering the competition, as well as at the time of

conferring the medal, shall be members of the American Medical Association. 5. The competition for the medal will be closed three months before the next annual meeting of the American Medical Association, and no essays will be received after March 1, 1898. All communications should be addressed to Dr. W. L. Rodman, chairman, 1626 Spruce Street, Philadelphia.

**The Health of the Army.**—In his annual report, Secretary of War Root compliments the medical and commissary departments of the army for efficient service rendered during and since the war. "The health of the army from the beginning of the Spanish war has," he says, "been remarkably good. The deaths from all causes (including casualties in action) in the whole army, regulars and volunteers, for the fourteen months from May, 1898, to June, 1899, inclusive, were 6,619. This is equivalent to an annual rate of 33.03 per 1,000 of strength. The deaths from disease during the whole period were at an annual rate of but 25.68 per 1,000. . . . For an army largely drawn from a cold climate and transported suddenly to the tropics, mainly composed of new recruits not trained to care for themselves in camp or on the march, and a great part of which was stationed in a malarial country or quartered in and about cities infected with yellow fever, and especially adapted to the production of typhoid, this is an extraordinary result and reflects credit upon all the branches of the service engaged in clothing, feeding, and caring for the men. The significance of the annual rate of death from disease in the Philippines (17.20 per 1,000) may be better appreciated by comparison with the rates in some of our well-known American cities. The annual death rate per 1,000 is in Washington 20.74, in Boston 20.09, in San Francisco 19.41, in New York 19.28, and in Baltimore 19.10."

**St. Catharine's Alumni Society.**—About twenty-five physicians, who in years gone by were attached to the house staff of St. Catharine's Hospital of Brooklyn, N. Y., have organized the Society of the Alumni of St. Catharine's Hospital, in order to keep up the pleasant memories associated with their connection with that institution. The officers elected at the first meeting were: *President*, Dr. Maurice Enright; *Vice President*, Dr. George Wieseckel; *Secretary*, Dr. James S. Slavin; *Financial Secretary*, Dr. William F. Linder; *Treasurer*, Dr. Michael J. Neville.

**Work of the Craig Colony.**—According to the annual report of the Craig Colony, recently submitted to the State board of charities, 95 new patients, 40 men and 55 women, were admitted during the past year, and 35 were discharged. The death rate for the year was the lowest in the history of the colony. Since its opening, February 1, 1896, 504 epileptics have been received at the colony, of which 378 remain. When the new buildings now in the course of construction are completed the capacity of the colony will be increased to a total of 720 beds.

**A Cuban Medical Congress.**—It is proposed to hold a medical congress in Cuba under the auspices of the Sociedad de Estudios Clínicos of Havana. The committee appointed by this society has consulted with members of other medical societies on the island, and representatives of those will soon meet to appoint an executive committee. The date and place of meeting will be decided by this committee. The first and only Cuban medical congress was held about ten years ago.

**Expectoration Cheaper in Hoboken.**—Some time ago an ordinance was adopted by the health board of Hoboken, N. J., imposing a fine varying from $10 to $25 upon any person who expectorated upon the floor of a street-car, ferryboat, or any other public conveyance or public building. The law was frequently violated, but no one was ever punished, and it was thought that the police refrained from making arrests because the public considered the penalty too severe for the offence. The health board has therefore reduced the fine to $3.

**Medical Matters in the South African War.**—The American committee to aid Red Cross work in the South African war has arranged to make use of the facilities offered by the Netherlands Red Cross, a responsible organization already in the field, insuring the prompt and effective use of every dollar contributed. According to a statement recently issued by the committee in this country, the Boers are badly in need of hospitals and hospital supplies, and it is to help make up that deficiency that the committee in the United States has been organized. The British army is well equipped with Red Cross facilities, but the Boers are almost wholly dependent upon volunteer physicians and surgeons, and on this account both the British and Boer wounded within the Boer lines must necessarily suffer. A party of medical students left Edinburgh recently to go out to South Africa under the leadership of Dr. Neethling, of Bradford, to act as an ambulance party in aid of the Boers. The scheme is said to have originated in the South African Union in Edinburgh, and is said to be financed by Sir James Sivewright. The men are all Cape Colony born and bred, and British subjects, though almost all of Dutch extraction. A Russian medical journal comments approvingly on the latter circumstance, and remarks that it would be hard to find such an instance of liberty of action in any other country than the now much-abused England.—The lepers who are confined on Robben Island have opened a fund for the sick and wounded soldiers. They have forwarded their first donation to Governor Milner.—The Queen has given a union jack to the hospital ship *Maine* as a sign of her gratification at the work of the American women who raised the funds for fitting out that vessel. The Duke of Connaught will present the flag on behalf of her majesty.—There have been many complaints that the Boers have persisted in shelling the town hall at Ladysmith which was used as a hospital and flew the Red Cross flag. The correspondent of the London *Morning Post* says that Commandant Schalk-Burger was notified of this, but the notification produced only further fire. Altogether twelve hospital attendants have been wounded and one killed, the correspondent

says. *The Daily News'* Ladysmith correspondent also reports that the Boers fired on the hospital, and he adds that the fire was intentional, since the town hall is not in line with any important camp or defensive work. The Boers, he says, assert that they are entitled to restrict the British to one hospital. In one case in which the Boers had shelled a hospital, it was found that the gunners did not know it was a hospital, it being impossible for them to see the Red Cross flag, and it is probable that a similar error occurred in this instance.

**The Army Transport Service.**—In his annual report the Secretary of War pays a high compliment to the management of the transport service of the army. The entire movement, he says, has been accomplished practically without loss of life, disease, or injury to health. The report of the quartermaster-general shows that during the fiscal year ending June 30, 1899, that branch of the service transported between Cuba, Porto Rico, Honolulu, the Philippines, and the United States, 202,587 passengers, 27,353 animals, and 86,150 tons of freight, and that transportation was furnished during the same period, by rail and water, exclusive of the army transport service, for 1,064,383 persons, 72,711 animals, and 544,644 tons of material. The efficiency and safety of this service, and the freedom from disease and accident which have characterized it, are very gratifying. The transport service on the Atlantic is conducted entirely by vessels owned by the government, which now make regular trips between New York, Havana, Santiago, and Porto Rico. They carried during the six months from January 1 to June 30, 1899, 45,507 passengers, 29,133 tons of freight, 2,449 parcels and pieces of baggage, and 6,558 animals.

**Still Another Tuberculin.**—The telegraph announces that "a Chicago physician has discovered a tuberculin that will cure (*sic*) consumption. It is a serum which, he says, will reveal the presence of tuberculosis before it can possibly be detected by the use of the ordinary means used by physicians."

**Bequests to Hospitals.**—The following charitable institutions in Paterson, N. J., received legacies of $5,000 each by the will of the late Vice-President Hobart: St. Joseph's Hospital, General Hospital, St. Joseph's Orphan Asylum, and the Paterson Orphan Asylum. The original bequest to each of these institutions was $3,000, but in each case the amount was raised to $5,000 by a codicil.

**A National Jewish Home for Consumptives** was opened and formally dedicated at Denver, Col., on Sunday, December 10th. The idea of establishing it was first publicly suggested by *The American Israelite* of Cincinnati, Ohio, and that paper has been efficient in furthering the plans for obtaining the needed support for the institution.

**Pennsylvania Hospital.**—The medical staff has been increased in number from four to six, and Drs. Frederick A. Packard and J. Alison Scott have been appointed to the new positions.

**Not Dr. Samuel Treat Armstrong.**—Dr. John Winters Brannan writes: "In the obituary notes in the MEDICAL RECORD of December 9th appears the name of Major Samuel T. Armstrong, who died at Manila on December 4th of leukæmia, according to General Otis' telegram. From the sketch given of the life of Major Armstrong it would seem that his name has been confounded with that of Dr. Samuel Treat Armstrong, who practised for some ten years in this city, and was appointed to the volunteer service of the army early in the late war with Spain. I have recently received a letter from Dr. Armstrong, dated November 5th, at Puerto Principe, Cuba. He was at that time in excellent health, to use his own words, and was chief surgeon of the troops in that department. He had no expectation of being assigned to other duty, and could hardly have made the journey from Cuba to Manila during the twenty-nine days' interval between November 5th and December 4th. By publishing this statement you will, I have no doubt, relieve the minds of Dr. Armstrong's many friends in this city and elsewhere."

**Further Gifts to the Lying-in Hospital.**—Mr. J. Pierpont Morgan, who some time ago gave $1,000,000 to the Society of the Lying-in Hospital for the erection of a new hospital building, has added to his donation the sum of $350,000 and two large lots which will give an increased area for building purposes of about four thousand square feet. The new building will be ready for occupancy in about a year, it is understood.

**Stoppage of Pay of a Transport Surgeon.**—The pay of the chief surgeon of the transport *Tartar* has been withheld pending an investigation to determine the responsibility for the wretched condition of the sick soldiers brought in the ship from Manila. In his protest filed at the War Department in Washington, the accused surgeon asserts that he was in no way responsible for the conditions prevailing on the *Tartar*, and that he was powerless to remedy the abuses which existed.

**Alumni Association of the German Hospital.**—The third annual dinner of the above society took place on Wednesday, December 6th, under the presidency of Dr. Franz Torek. After an address of welcome by the president, in which he commented upon the progress of the association and of its individual members during the past year, Dr. Abraham Jacobi addressed the society, his subject being "The Hospital Interne." He was followed by Dr. Herman G. Klotz, who related "Reminiscences from the Early Period of the German Hospital." Dr. Henry J. Wolf spoke on "A Few Early Troubles and Errors."

**Medical Practice in Italy.**—It is reported that the Italian prime minister has promised a deputation of native physicians that he will introduce in the session of parliament, which has just begun, a bill to prohibit practice, even among their own countrymen, by medical men who do not hold Italian degrees, unless the country of their qualification concedes reciprocal rights of practice to Italian graduates. This is, on the face of it, a perfectly fair proposal of reciprocity,

but it is one which it would hardly be to the interests of any Italians, barring the physicians, to carry into effect. One of the chief sources of Italy's income is the money spent by English and American visitors, and the number of these would be very materially reduced if they were unable to secure the services of an English-speaking physician in case of illness. The Italian parliament will not be likely to adopt such a penny-wise pound-foolish policy.

**Scarlet Fever** has appeared at Wellesley College, two of the students being ill. The college has been closed until after the Christmas holidays.

**The Phœnixville (Pa.) Medical Association,** at its meeting on December 6th, elected the following officers: *President*, Dr. F. D. Emac; *Vice President*, Dr. William B. Wynne; *Secretary*, Dr. E. J. Hadfield; *Treasurer*, Dr. Albert Wenks; *Censors*, Drs. Doran, Shoemaker, and McWhinney.

**The Medical Society of the State of New York.**—The president of this society has appointed the following business committee to which all communications concerning papers to be presented at the next annual meeting, January 30 to February 1, 1900, should be sent: Dr. Wendell C. Phillips, chairman, No. 350 Madison Avenue, New York City; Dr. Henry L. Elsner, Syracuse; Dr. Chauncey P. Briggs, Ithaca.

**The Army Ration.**—Colonel Charles Smart, deputy surgeon-general, has made a report on the army ration, in which some of the criticisms against it are answered. He says that it is the product of experience of several generations of army officers, and he thinks it the part of wisdom not to urge alterations until they have been proved to be improvements. He holds that the advantage of the ration lies in the fact that the soldier can take almost any kind of fresh meat within his reach in lieu of bacon, and can supply himself plentifully with fruit and vegetables, and even luxuries, by the commutation into cash of the considerable portion of the ration over and above that required for his dietary.

**Honors for General Wood.**—The President has promoted Gen. Leonard Wood to be major-general of volunteers, and he now outranks, it is said, all the United States officers in Cuba with the exception of General Brooke. Upon the latter's retirement next year General Wood will undoubtedly be appointed governor of the entire island. General Wood has definitely put aside a medical career, and has cast his lot with the line of the army, and while we cannot but regret the loss of such a man to the profession of medicine, it is evident that he has chosen wisely, and has adopted a career in which his administrative talents can best be exercised.

**College of Physicians of Philadelphia.**—At a stated meeting held December 6th, Dr. Louis F. Atlee, late surgeon on the U. S. S. *Olympia*, and Dr. Simon Flexner, of the Johns Hopkins Philippine Medical Commission, presented communications on "The Medical Conditions Existing in the Philippines." Dysentery is perhaps the most serious disease, and a bacillus thought to bear an etiological relation was isolated. Scabies is exceedingly common. The malarial fevers prevail in moderation. Typhoid fever also occurs, as do leprosy and beri-beri. Dr. John K. Mitchell presented to the college a copy of a picture of Sydenham, obtained by permission of the Royal College of Physicians and Surgeons of London.

**Philadelphia Hospital Physicians.**—The thirteenth annual dinner of the Association of Ex-Resident and Resident Physicians of the Philadelphia Hospital (Blockley) was held on December 5, 1899. Addresses were delivered by Drs. Raymond Spear, William H. King, McGlynn, E. W. Holmes, and J. Chalmers Da Costa.

**Navy Department,** Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending December 9, 1899. December 1st.—Medical Director D. Dickinson promoted to medical director. Medical Inspector G. E. H. Harmon promoted to medical inspector. Passed Assistant Surgeon A. W. Dunbar detached from the *Resolute*, when placed out of commission, and ordered home and to wait orders. December 5th.—Assistant Surgeon R. K. McClanahan ordered to the Washington navy yard. Assistant Surgeon W. M. Garton detached from the Washington navy yard, and ordered to the *New York*. Assistant Surgeon D. N. Carpenter ordered to the Boston navy yard.

**Professor Felix Victor Birch-Hirschfeld,** who has long filled the chair of general pathology and pathological anatomy at the University of Leipsic, died on November 20th, at the age of fifty-seven years.

**Obituary Notes.**—Dr. Stuart B. Carlisle, of Mount Vernon, N. Y., died in the Harlem Hospital in this city on December 8th. He had suffered for some time from cardiac trouble, and this was the cause of his death. He was born in this city in 1848, and was graduated from the Bellevue Hospital Medical College in 1881.

Dr. William A. Lockwood died in Brooklyn on December 8th, of poison which he had taken with suicidal intent. He was fifty-five years old, and was a graduate of the College of Physicians and Surgeons, New York, in the class of 1864. He was in practice for several years in Norwalk, Conn., later had an office in this city, and recently moved to Brooklyn.

Dr. William Pitt Brechin, of Boston, died on December 10th, of septicæmia, at the age of forty-eight years. He was a graduate of the Harvard Medical School in 1872. Dr. Brechin was also justice of the peace for Suffolk County.

Dr. Adeline Martin Rea, of York, Pa., wife of Dr. Charles Rea, died recently. She was a graduate of the Woman's Medical College of Pennsylvania in the class of 1893.

Dr. Frederick L. Johnson died at his home in the Borough of Queens on December 10th, at the age of thirty years. He was a graduate of the Medical Department of the University of Pennsylvania in the class of 1890.

## Therapeutic Hints.

**Slight Bronchitis** attended with nausea in influenza:

℞ Morph. sulph. ..... gr. ss.
Acidi hydrocyanici dil ..... ♏ viij.
Spt. chloroformi ..... ʒ iss.
Aquæ menth. vir ..... ad ʒ iss.
M. S. Teaspoonful every three or four hours.

—*Jour. A. M. A.*

**Blepharitis Ciliaris.**—

℞ Antimonii sulphat ..... 1 gm.
Saxolene ..... 4 "
Petrolati ..... 2 "
M. S. For external use.

—Carra.

**Neuralgia.**—

℞ Ext. hyoscyami ..... 0.12 cgm.
Ext. valeriani ..... 0.20 "
Morph. hydrochlor. ..... 0.01 "
Pulv. glycyrrh. ..... q.s
For one pill. One morning and night—not more than three in twenty-four hours.

—Bastié.

**Pertussis.**—In infants below the age of one year apply to the pharynx:

℞ Ac. phenic. crystal ..... 1.50 gm.
Glycerini puri ..... 10. "
Syr. tolutani ..... 5. "

For older children:

℞ Ac. phenic. crystal ..... 1 gm.
Glycerini ..... 15 "
Sol. cocain. hydrochlor. (two per cent.) ..... 5 "

—Guida.

**Saline Injections in Tuberculosis.**—Landouzy thinks saline injections exert their beneficial effects by reason of reflex action on the nervous system. Dr. Morard (*Jour. de Méd.*, November 12th) employs the following formula for small doses:

℞ Sod. phosphat. ..... 5 gm.
Potass. phosphat ..... 5 "
Sod. chloridi ..... 4 "
Sod. sulphat ..... 20 "
Aq. dest. ..... 200 c.c.

**Measles.**—

℞ Ichthyol ..... 30 parts.
Axungiæ ..... 90 "
M. S. Apply twice daily to remove the eruption promptly or by early application prevent its coming out.

—Stizover, *Memorabilia*, No. 1, 1899.

**Percutaneous Medication** by salicylic acid is recommended by the editor of *Treatment*, November 9th, in acute articular rheumatism. He employs:

℞ Acidi salicylici,
Ol. terebinth.,
Lanolini ..... āā 10
Adip. suill. ..... ad 100

This is not to be rubbed in, causing desquamation, but spread on "calico" and kept in position by means of flannel bandages. It is absolutely useless in blennorrhagic arthritis.

**Injection of Osmic Acid** is advocated by Dr. W. H. Bennett for the relief of certain forms of neuralgia (*The Lancet*, November 4th). The nerve, having been exposed at the spot indicated by as small an incision as possible, which in the case of the supra-orbital, infra-orbital, or mental branches need rarely exceed half an inch in length, is hooked up for purposes of fixation. The solution of osmic acid (1.5 per cent.), freshly prepared, is injected by means of a sterilized hypodermic syringe, the needle of which is passed along in the substance of the nerve as far as it can be made to go. The total amount injected should be from five to ten minims, and it should be introduced in two or three separate injections in order that the whole nerve may be as much as possible soaked in the solution. During the injections a pledget of sterilized gauze or wool should be firmly held around the needle at the orifice of the wound in order to prevent the escape of fluid externally.

**Convulsions** in a child should always lead to systematic exploration of the thorax.

**Gonorrhœa in the Female.**—The most effective antigonorrhœal remedies so far known are ichthyol and the silver preparations. Ichthyol has a beneficial action, especially in cases of acute gonorrhœa in the female, and in my clinics every case of acute vaginitis and vulvitis easily yields to a few applications of tampons dipped in a preparation of ichthyol and glycerin, equal parts.—Ravogli, *Medical News*, November 18th.

**Phosphorus.**—We should be none the poorer if phosphorus were to be banished from our pharmacopœias. It has disappointed everybody who has tried it, and it is too dangerous a drug to be put into the hands of lay persons, in poisonous quantities, as one is obliged to do in out-patient practice, where it is usual to dispense a week's or a fortnight's supply. If phosphorus is to be prescribed at all, the patient taking it should be admitted as an in-patient, or be seen frequently. This seems to be the only lesson which can be learnt from the unfortunate case of poisoning in a baby recently reported by Dr. Koplik in *Pediatrics*. —*Treatment*, November 9th.

**Toxic Cumulative Effects of Sulphonal and Trional** were observed in a case reported by Bampton (*The British Medical Journal*, November 4th). As to treatment the reporter says: "I have been informed by the Clinical Research workers that it is not generally known that the only treatment of any avail for sulphonal poisoning is the free exhibition of alkalies. Where there is vomiting the difficulty is to get the alkali taken in sufficient quantity. The intravenous or interstitial transfusion of an alkaline solution might be tried. It is lamentable that such powerful drugs as sulphonal and antipyrin in bottlesful are allowed to be sold to the public for secret self-drugging purposes."

**Headaches.**—The treatment of the paroxysmal uric-acid headache is the clearing of all available uric acid from the body and blood, and this is accomplished by: (1) Avoiding food or drinks which contain uric acid or xanthin; (2) not taking more nitrogenous food than physiology requires; (3) clearing out stores of uric acid already in the body from neglect of (1) and (2). (1) Means the avoidance of all animal foods except milk and cheese, and of certain vegetable substances rich in alkaloids (as tea, coffee, etc.); (2) means taking enough albumin to produce from 3 to 3.5 grains of urea for each pound of body weight per day, but not more; (3) is generally sufficiently provided for by the change of diet, but occasionally it is necessary to give a course or courses of salicylates to aid elimination.—Alex. Haig, *The British Medical Journal*, November 4th.

**Vaso-Dilators** in general, including nitroglycerin, produce distressing symptoms which include palpitation, headache, at times quite severe and persistent, dizziness, tinnitus aurium, dilatation of the pupils, hæmaturia, choreic movements, and, in large dose, weakness in the legs, nausea, and vomiting.—C. R. Marshall (*Medical Chronicle*, September).

[In recommmending nitroglycerin for xeroderma in a boy of nine years Dr. Baskett (*British Medical Journal*, November 4th) speaks of it as an innocuous drug.—Ed.]

# Clinical Department.

## TOTAL ANIRIDIA: TWO CASES, ONE TRAUMATIC, ONE (WITH ECTOPIA LENTIS) CONGENITAL.

By GEORGE H. COX, M.D.,

NEW GLASGOW, NOVA SCOTIA,

LATE INSTRUCTOR IN DISEASES OF THE EYE, NEW YORK POST-GRADUATE MEDICAL SCHOOL.

Case I.—Mrs. M——, aged thirty-six years, bending forward in a dark room, forcibly struck some object which smashed her left eye-glass and drove the pieces into her open eye. When seen two hours afterward there were found a number of radiating wounds of the cornea corresponding to the sections into which the glass had been broken. They were all superficial but one, which extended over into the sclera, and seemed to have perforated the cornea near its centre. This perforation was very small, less than a line in length. There was no prolapse of iris, and the eye was not collapsed. The anterior chamber was filled with blood, so that the view of the deeper structures was completely masked. Vision amounted to faint perception of light. Treatment consisted in cleansing the conjunctival sac, the instillation of two drops of a gr.-ii. solution of atropine sulphate, and a bandage. A superficial examination of the eye two days later showed that the wound was practically healed, though the anterior chamber was still filled with blood. The action of atropine was explained to the patient, and she was told to expect that the pupil would be found to be enlarged when it became visible, but would regain its usual size in the usual time. But ten days later she called to report that, although the eye was healed and clear, the pupil remained very large. Examination showed a pupil the size of the whole cornea; in fact not a single trace of iris tissue was to be found on the closest inspection. A slight stellate opacity of the anterior part of the lens capsule was discovered (which in time completely cleared up), but the lens itself was undisturbed in position. Its periphery was in full view, showing as a circular dark line. The fibres of the suspensory ligament could be made out by proper illumination, outside of which the tips of the ciliary processes showed plainly in a scalloped row. (Fig. 1.) Vision is somewhat impaired by irregular astigmatism, and the patient suffers considerable disturbance from the diffusion of light, but the retina seems to be becoming more tolerant. She wears a dark smoked lens over the eye in bright light. The eye is perfectly quiet, and no untoward results have appeared in the eight months since the accident.

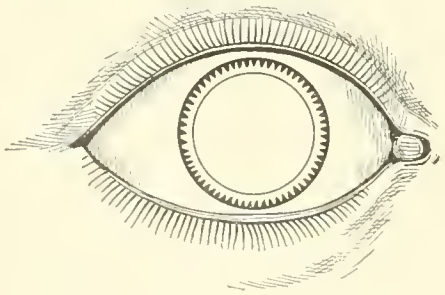

Fig. 1.

The fate of the avulsed iris in this case is uncertain. The family physician, who saw the case a few minutes after the injury took place, saw no trace of it in the wound or anywhere else. The corneal wound seemed too small to allow of its escape. Certainly, when I saw it twelve days afterward there was no trace of it inside the eye. The only explanation is that it was digested along with the blood by the aqueous humor and absorbed. The mechanism of the production of a total irido-dialysis involves the application of a sudden blow to the cornea. The force of this transmitted backward by the aqueous humor, while with the flattening of the cornea the ciliary circle is stretched and the periphery of the iris placed under great tension, causes the iris to yield at the latter point. Hemorrhage necessarily accompanies such an accident, and may be very severe, but in the case above described it was slight.

Case II.—Andrew McD——, aged fourteen years, although not complaining of poor vision, sees very poorly. The exact measurement of his vision could not be taken owing to his poor mental development, but it is very low even when his optical error is corrected. He is unable to read or write, does not know the letters or figures, but in many other ways is fairly intelligent. His dentition is extremely irregular, and the shape of his skull abnormal. Both eyes are symmetrically affected. He has a rapid lateral nystagmus. Not a vestige of iris is to be found in either eye. The lenses are displaced vertically upward to such an extent that their centres lie at the level of the upper corneal border. (Fig. 2.) They are both cataractous. All the other media are clear. The supporting zonule is absent from that part of the periphery of the lenses which is visible. The lenses swing forward and backward with the motions of the eyes, as if hinged above. The anterior half of the vitreous is fluid. In the left eye, under low ateral illumination with the ophthalmoscope, an appearance may be made out below as of faint, transparent, fringe-like fibres half a line in length, possibly remains of the lower part of an original zonule. Even this is absent in the right eye. No sign of the presence of a ciliary body can be made out in all that part of either eye which is visible to the ophthalmoscope.

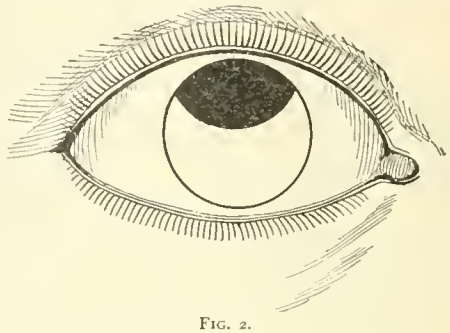

Fig. 2.

The conditions noted are represented schematically in the accompanying illustration.

---

**Blood-Letting in Gynæcological Cases.**—Dr. Bedford Fenwick (*Medical Times and Hospital Gazette*, November 25th) writes as follows: "In general terms the methods which I have found most suitable and which give the greatest relief by local blood-letting are: (1) By scarification of the cervix when that part presents a deep-red, bluish, or purple appearance, evidencing much or long-continued congestion of the uterus, always remembering, of course, to make sure that the condition is not due to pregnancy; (2) by cupping or leeches over the ovaries, when throbbing, burning pain in these regions is the chief or only symptom; (3) by leeches around the anus in cases where the *fons et origo mali* evidently is the presence of inflamed hemorrhoids, prolapsus recti, inflamed carunculæ myrtiformes, and such-like congestive conditions."

# Society Reports.

## THE SOUTHERN SURGICAL AND GYNÆCOLOGICAL ASSOCIATION.

*Proceedings of the Twelfth Annual Meeting, Held at New Orleans, La., December 5, 6, and 7, 1899.*

*First Day, Tuesday, December 5th—Morning Session.*

THE association met at the St. Charles Hotel, and was called to order by the president, Dr. Joseph Taber Johnson, of Washington, D. C.

An address of welcome was delivered by Dr. Henry Dickson Bruns on behalf of the local profession, which was responded to by President Johnson.

Dr. Ernest S. Lewis, chairman of the local committee of arrangements, made a brief report as to the work of the association, entertainments, etc.

**Myomatous Tumor of the External Iliac Vein, with Report of a Case.**—DR. A. M. CARTLEDGE, of Louisville, Ky., presented a paper with the above title. Myomatous tumors arising from the muscular coat of the veins constituted one of the rarest of pathological curiosities, as a faithful search of the literature by the essayist discovered but two cases reported. A brief report of these was given. His own case occurred in a woman, aged fifty-three years. Five years ago the patient suffered from swelling of the left leg, extending from foot to hip; it came on gradually, and the limb attained a considerable size; the swelling subsided in eight or ten months. She had pain at this time in the left iliac region low down. No enlargement was noticed. Two years ago the patient noticed a small lump just above Poupart's ligament on the left side, from which she suffered some pain. Within the last year the pain had been much greater in the left iliac region, and the enlargement more distinct and very hard; latterly she had been losing much flesh. She had slept poorly on account of pain, and also suffered from accumulations of gas in the bowels. A diagnosis of carcinoma of the deep inguinal glands above Poupart's ligament was made, probably due to some primary, yet undiscoverable carcinomatous lesion in the bowel or uterus. Exploration of the iliac tumor was advised for a more positive diagnosis, and removal, if found expedient. This was accepted, and the operation was performed on March 9, 1899. The operation consisted of an incision five inches in length, beginning near the external abdominal ring, and running one inch above and parallel with Poupart's ligament, which came in contact with the tumor after opening the fascia of the external oblique muscle. The anterior part of the tumor occupied the inguinal canal; the round ligament was easily identified in front of the tumor, occupying the most fantastic relation to it, wound as it was in and out around several lobules of the tumor; it was separated easily and pushed to the inner side. It was now seen that the tumor was not of glandular origin. By blunt dissection it was gradually freed from its upper and lower and external bed. The outer and deeper attachments were approached with great concern, as they were evidently in the closest relation with the external iliac vessels. Up to this time no vessels of importance had been encountered. It had been expected to meet with the deep epigastric, but it nowhere appeared. Gentle and careful blunt dissection carried the pelvic peritoneum upward, no buttonholing of the same occurring. After reaching the base and upper and outer part of the growth the external iliac artery could be plainly felt entering the tumor. Search to the inner and posterior aspect of the artery failed to demonstrate definitely the vein; nothing more than a fibrous thickening could be made out, which was lost in the tumor substance. The point at which the external iliac artery entered the growth was about two inches above its lower termination. The apparent obliteration of the vein, and its elimination as a factor in any surgical procedure affecting the circulation of the limb, determined the operator to ligate the artery one-half an inch above where it entered the growth. The fibrous remains representing the vein were similarly treated. The tumor was now separated from above downward, the deepest projection being disembedded from the obturator foramen; it now remained only attached to the vein and artery beneath Poupart's ligament. These were freed from the surrounding structures by blunt dissection, and were ligated separately and the tumor was removed. In cutting the vein below where it entered the growth it was manifest that its lumen was almost obliterated, barely admitting a good-sized needle. The tumor was removed entire, with not a lobule broken, and passing through it and removed with it were one and three-quarters inches of the external iliac artery, and the same length of the nearly obliterated vein. The only hemorrhage of any account was from the obturator vein, where it passed through the foramen; this was easily secured by ligation. The vessel was much enlarged, as a result of participating in a long-established collateral venous circulation. The upper portion of the incision was closed by tier sutures, the lower portion being left open and being occupied by a gauze drain, which was placed down to the obturator foramen. The patient was progressing toward recovery.

DR. WILLIAM E. PARKER, of New Orleans, referred to the difficulty of diagnosticating tumors below the groin.

**Ureterectomy.**—DR. J. WESLEY BOVÉE, of Washington, D. C., read this paper. He said that surgery of the kidney was practically of recent date; and surgery of the ureter was the logical sequence to renal surgery. The paper considered essentially the subject of ureterectomy, an operation less than nine years old, one seldom indicated, but offering brilliant results. Dr. Bovée reported the following case:

Mr. J. J. T——, forty-eight years of age, was first seen with Dr. E. Reisinger, of Washington, in August, 1898. Three years previously his left kidney had been removed for a renal abscess, and subsequently another operation had been done by the same surgeon for the remaining pus tracts and severe localized pain. He told the essayist that he had been an invalid constantly, before and since the first operation, and begged for relief. He had never been without pain, and was frequently obliged to resort to the use of morphine. He was found to be in a very much enfeebled condition, his pulse ranging from 110 to 130, and his temperature from 99° to 101.6° F. On the left anterior and lateral aspects of the abdomen, slightly below the level of the umbilicus, were two scars of the previous operations. One of them was so near the median line that he was inclined to think the nephrectomy had been made transperitoneally. A large hernia had occurred at this site. There were three sinus tracts in the left lumbar region discharging a thin, watery pus. In spite of the general weakness of the patient an exploration was decided to be advisable, and accordingly on August 17, 1898, after free stimulation, he was anæsthetized. With the assistance of Dr. Reisinger a careful exploration was made through an extra-peritoneal incision, reaching from just above the level of the upper fistulous opening and in front of the left quadratus lumborum muscle to an inch inside the anterior superior iliac spine. By careful dissection and holding probes in the fistulæ the former location of the kidney was reached. Instead of the kidney a large amount of adipose tissue, containing many pus tracts and cal-

culi and much cicatricial tissue, was found, and a little below it was the upper end of the ureter surrounded by calculi and thickened pus. The ureter was about one inch in diameter and filled with cheesy pus and calculi. It was resolved to remove the duct, and immediately the incision was extended along to the inguinal canal, keeping about one inch from Poupart's ligament. With considerable difficulty, but with very light loss of blood, the ureter, in pieces, was removed to the bladder wall. The distended lumen ended abruptly about half an inch from the bladder wall, this portion being a solid cord. The wound was closed with through-and-through silkworm-gut sutures, a strip of iodoform gauze being passed to the lowest point of the pelvis wound and brought out at the lower end of the external incision, and another strip in the space formerly occupied by the kidney. The unusual atmospheric high temperature and humidity probably assisted in producing the fatal issue seventeen hours later.

Dr. Samuel E. Milliken, of Dallas, Tex., called attention to a point in technique adopted by Kelly—namely, instead of making one incision, he left a bridge of abdominal wall, making the first incision from the twelfth rib down to the crest of the ilium in front of the lumbar muscles, with a second incision along the inguinal region. This enabled the operator to expose the kidney, to make a thorough examination, and also to trace the ureter.

Dr. Bovée, in reply to Dr. Milliken, said there might be the advantage in two short incisions over one large one, of having a less amount of tissue to cut across, as muscles, fascia, etc., but he thought there was a drawback in having to dissect through a smaller space to loosen the ureter between the two incisions. Such an operation would require more time, which, in many instances, is a precious element. However, he was not disposed to criticise Dr. Kelly's method, because he had never tried it.

**Serious Complications Following Passage of the Urethral Sound.**—Dr. William E. Parker, of New Orleans, read a paper with this title. He reported the case of a man with stricture of the urethra who passed urine with difficulty. The first time a sound was passed he had a chill, with a temperature of 105° F. After a week the sound was passed again, no fever having occurred between the days of passage of the sound. In the mean time he had the man's urine examined, with a report showing the specific gravity to be 1.020, one-half per cent. of albumin, no casts, pus, and reaction acid. After the passage of the sound the second time, the man had a urethral chill, suppression of urine, and died with uræmic convulsions the following day, *i.e.*, the second day after the passage of the sound, although the usual precautions had been taken to prevent urethral chill. The autopsy showed that there was intense congestion of both kidneys, with pus in the pelvis and in the calyces of the left kidney.

Dr. William P. Nicholson, of Atlanta, Ga., had seen a number of cases of severe chill following the introduction of sounds, in which all the necessary precautions had been taken. He had observed six cases of swelled testicle following the introduction of the sound, but had not seen a fatal case. In a book on the "Calamities of Surgery," Sir James Paget mentioned a case in which the introduction of the catheter caused suppression of urine and death of the patient. The experience of genito-urinary surgeons would show that no matter how careful they were in sterilizing instruments, etc., in many cases the apparent nervous connection between the organs would produce a severe chill and, in some cases, suppression of urine.

Dr. W. F. Parham, of New Orleans, believed that post-mortem examinations would show, in cases in which death had occurred after the passage of the urethral sound or catheter, some form of nephritic trouble, usually the interstitial. He recalled the case of a man upon whom he had operated for strangulated hernia, who had given no history of any renal trouble, yet the patient died of interstitial nephritis, as verified by an autopsy.

Dr. Manning Simons, of Charleston, S. C., said he had met with a number of cases in which the passage of the sound was followed by trouble. It was his routine practice, when a man presented himself for the first time, in whom he had to pass the sound, to administer a grain of opium, and ten grains of quinine immediately after its passage as a prophylactic measure against urethral chill and fever. He thought the cases should be divided into three classes: first, those in which the trouble was reflex from the nervous system; second, those in which urethritis was set up by unclean sounds; third, those in which there was serious disease of the kidney, but which was not discovered preceding the use of sounds.

Dr. J. D. Bloom, of New Orleans, narrated two fatal cases from the passage of the sound, in New Orleans, and these showed kidney lesions post mortem.

Dr. F. W. McRae, of Atlanta, reported a fatal case which occurred in the practice of the elder Westmoreland while the speaker was a medical student. He had seen complications follow the introduction of the sound. During the last five or six years he had not introduced a sound, except in the direst emergency, without having the patient under observation for several days thereafter. His results had been better since paying particular attention to careful preparation of the patient and the instruments, repeated examinations of the urine, etc.

**Gunshot Wounds of the Abdomen.**—Dr. H. H. Grant, of Louisville, Ky., read this paper. He stated that the surgery of gunshot wounds of the abdomen, which had been for some years pretty well settled to the satisfaction of the profession, received something of a shock by the report of the surgeons who served in the late war with Spain (*Journal of the American Medical Association*, July 11, 1898). Though these reports, which were made by men of experience and high reputation on the subject, were modified to bear especially on the wounds received in battle, yet the inferences, and indeed the conclusions, affected to a considerable degree surgical judgment. The results of the investigation of Klemm showed, in an analysis of one hundred and fifty-two cases, that even those patients in whom penetrating wounds of the abdomen were established, who did not die of immediate effects, eventually nearly all succumbed to exhaustion from sepsis and later suppuration. The meaning of this was that, practically speaking, all cases of penetrating gunshot wounds of the abdomen, untreated by surgical repair of the lesion, resulted fatally, from hemorrhage, peritonitis, or sepsis. The mortality after operations done in the first seven hours after injury was fifty-two per cent., as against sixty-four per cent. for operations at all periods. But a study of the tables of Parker showed such variations in the mortality succeeding complicated and uncomplicated wounds of the various viscera, all of a fatal character without operation, as to indicate that in uncomplicated wounds in some situations the early operator would save from seventy-five to eighty per cent. of what would otherwise be fatal cases. His tables also showed that of sixteen operations done in which no intraperitoneal injury was found, but three patients died, one from an overlooked perforation and two from peritonitis, due to infected blood clot, a fatal complication upon which Klemm laid much stress. Dr. Grant sent out a circular letter to one hundred prominent surgeons, and an analysis of the reports developed a number of most important and interesting facts. The mortality of the whole number

of operations was about fifty-two per cent., an indication that the prognosis was improving with the more energetic measures of treatment. The practical management of suspected penetrating wounds was as plain a duty as the tying of a bleeding artery, in his opinion. As soon as possible after the injury the patient should be transported to a suitable place, and, under aseptic precautions, after all preparations have been made for a laparotomy and repair of lesions, the experienced hand should carefully trace the course of the bullet into the cavity, if it went there. This was easy enough when the penetration was direct from the abdominal wall, but was often difficult or impossible when it was from behind or from the thoracic or pelvic cavity. Under these latter circumstances the history of the direction of the projectile, and the general symptoms, must be the only guide, giving to the side of operation the benefit of the doubt.

Dr. Hugh M. Taylor, of Richmond, Va., said he had operated on three cases of gunshot wounds of the abdomen within the last two or three years. He laid stress on the utter hopelessness of cases until an operation was done. Of course, he was aware that arguments had been advanced by good men against surgical interference in many cases. It was not always easy to satisfy the attending physician, in the absence of serious symptoms, that an exploratory incision was imperative. Of the three cases narrated by him, one was saved.

Dr. William E. Parker was glad to note that the percentage of recoveries from operative interference in gunshot wounds of the abdomen was improving. Cases occurring in civil life should be operated on as soon as possible. In military life he had taken the stand that, with the modern small-calibred bullet, as many cases would result in recovery without operation in the field as with it. He mentioned a case operated on by the late Dr. Miles in which there were fourteen intestinal perforations, which were closed, and the patient recovered.

Dr. Manning Simons had operated on twenty cases of gunshot wounds of the abdomen by laparotomy, and of this number he saved three. One was a gunshot wound of the stomach, the operation having been done within a few hours after the occurrence. There were two perforations, one of entrance and one of exit, the bullet having lodged in the muscles of the back. This patient, a boy, recovered and was well to-day. In one of the cases there were fifteen perforations of the bowel. In some he had resected as much as two feet of the small intestine.

Dr. Samuel E. Milliken had encountered one case of gunshot of the abdomen in a child, seven years of age, who had received the contents of a shotgun. He did a laparotomy, and the child recovered.

Dr. J. D. Bloom said the diagnosis of penetrating wounds of the abdominal viscera was very essential in deciding upon an operation. He mentioned the case of a man who was brought into the Charity Hospital, in which it was thought the peritoneal cavity had been penetrated, but laparotomy disclosed that there was no penetration. He recalled a number of cases in which the patients recovered when the operation was done within twenty-four to thirty-six hours after being shot.

Dr. W. F. Parham said it was difficult in many instances to determine the exact location of the wound in the abdomen; therefore the surgeon should study the character of the wound itself, its direction, the circumstances connected with the shooting, the distance between the combatants, etc.

Dr. W. E. B. Davis, of Birmingham, Ala., said the question to be settled was whether every case of penetrating wound of the abdomen should be operated upon. He believed every such case should be so treated. The surgeon should examine carefully the wound of entrance so as to determine, if possible, if penetration had taken place. He condemned the Senn gas test, and said that the teachings of this eminent surgeon in regard to gunshot wounds of the abdomen were harmful, in that they had created a sentiment which made it exceedingly difficult in certain communities to operate on cases of penetrating wounds of the abdomen, because, if the patient should die, the surgeon would be censured, and discredit would be cast upon surgery. He and his brother (Dr. John D. S.) had operated on a number of cases of penetrating wounds of the abdomen from time to time.

Dr. F. W. McRae had seen and operated on five cases of gunshot wounds of the abdomen at the Grady Hospital. The point of entrance of the bullet was above the umbilicus, the injury having been received when the patient was standing, and in every one of them there were numerous perforations of the hollow viscera. In military practice, he said, wounds were received by soldiers who had been fasting for a number of hours, and the intestines were empty; extravasation was not so likely to occur. On the other hand, in civil practice wounds were almost always received under conditions of more or less debauchery, when the stomach was loaded with whiskey, beer, food, Limburger, etc.; consequently extravasation of the contents took place rapidly, and death was much more apt to take place. He considered the Senn gas test worse than useless, it being merely corroborative, not conclusive as to penetration of the viscera.

Dr. Grant, in closing, said he had enunciated a few surgical principles, and he hoped the members would conclude that it was as much the duty of the surgeon to operate on a penetrating wound of the abdomen as it was in cases of strangulated hernia.

---

*First Day—Afternoon Session.*

Dr. Rudolph Matas, of New Orleans, presented a paper in which he gave the history of pulmonary insufflation and artificial respiration in intrathoracic surgery by intubation of the larynx. He exhibited an apparatus, and demonstrated its application. In summing up the peculiarities of the apparatus he had shown he called attention to the following points: the original O'Dwyer cannula, while retaining its intralaryngeal portion unchanged, is modified so that it may be utilized, first, as a respirator; second, as a tampon cannula; third, as an anæsthetizer; fourth, as a tractor on the tongue; fifth, as an insufflator; sixth, as an aspirator.

**Recto-Vaginal Fistula.**—Dr. Lewis S. McMurtry, of Louisville, Ky., read a paper on this subject. He said that, excluding cancer extending from the cervix uteri, recto-vaginal fistula was due to traumatism, not to the compression of the tissue as in vesico-vaginal fistula, but to extensive rupture of the perineum involving the recto-vaginal septum, cicatrizing inferiorly, but leaving a perforation above where the septum was thin and permitted contact of the vaginal and rectal mucous membranes, thus uniting these membranes and making a permanent opening. Wounds made in instrumentation through the vagina, and the pressure of foreign bodies retained in the vagina sufficiently long to produce ulceration and necrosis, were among the rare causes of this lesion. The most common site was in the lower portion of the vagina, just above the sphincter muscles, and at the point already indicated where the septum was thin and the mucous surfaces were in close proximity one to the other. The opening was usually very small, and the mucous membrane was reflected around like a fringe, making its detection more amenable to touch than to sight. The method usually employed in the repair of vesico-

vaginal fistulæ, whereby the edges are freshened in a funnel-shaped denudation, would rarely succeed in repairing a recto-vaginal fistula. The action of the anal sphincter, the penetration of fecal matter, and the sparse layer of tissue, prevented repair by this method. The divulsion of the sphincter muscle would not suffice, in the larger proportion of cases, to overcome this obstacle to success. Extensive cicatricial deposit was another obstacle to repair by this simple procedure. The operation in consequence was resolved into a modified perineorrhaphy, by which the fistula was transformed into a complete tear of the perineum. The method of flap-splitting popularized by the late Mr. Lawson Tait was pre-eminently applicable to this procedure. By this method broad surfaces were supplied without loss of tissue, permitting gliding of the vaginal and rectal orifices of the fistula so as to interpose firm and healthy tissues. In exceptional cases, in which the fistula was so low down as to be within the grasp of the sphincter, it would be best to divide the septum vertically, freshening liberally the margins of the fistula, and suturing the surfaces as in complete laceration of the perineum. In a very limited class of cases, in which the fistula was small and the cicatricial deposit was not extensive, a simple denudation and suturing after divulsion of the sphincter ani muscle might succeed. The flap-splitting method already mentioned would be found most applicable and should be preferred for general application. Vertical division of the septum should be the first step of the operation in low fistulæ with extensive cicatricial deposit, and the operation was then resolved, after paring the edges of the fistula, into the operation for complete tear of the perineum. It would rarely be necessary to use buried sutures; when used, these should be of catgut and should be introduced after the Lembert plan. As already stated, the flap-splitting operation of Tait had the greatest field of usefulness in this procedure. The following case was of special interest, both on account of the unique cause of the fistula, and the consequent deduction that a very simple and common gynæcological appliance was not without danger under certain circumstances:

Miss C. W——, aged thirty-one years, never married, a teacher, was subject to a backward displacement of the uterus. In August, 1899, she applied to a physician for treatment, and a metallic pessary of the Hodge pattern was inserted. The pessary was placed in position on a Thursday by the physician who had referred the case to Dr. McMurtry, and the patient returned to her home, some thirty miles distant from the physician. On the second day the patient began to suffer pain, which increased day by day, and when she was examined by the physician on the Monday following, the pessary was found protruding into the rectum and was removed per anum. When the patient was referred to him on October 6th, there was an opening in the recto-vaginal septum just above the anal sphincter, of oval form, that would readily admit the end of the little finger. The operation consisted of divulsion of the sphincter, separation of the vaginal mucous membrane, freshening the edges of the fistula, and suturing with Lembert sutures of catgut the rectal portion of the fistula, gliding and suturing the vaginal mucous membrane. Union was prompt and perfect, and the patient was now quite well.

In the discussion cases of recto-vaginal fistula were reported by Drs. T. J. Crofford, of Memphis; George Ben Johnston, of Richmond; George H. Noble, of Atlanta; W. D. Haggard, Jr., of Nashville, and J. Wesley Bovée, of Washington, D. C.

Dr. C. Jeff Miller, of New Orleans, read the report of an interesting case of what he and others considered an ossified uterus. He presented the specimen.

*Second Day—Wednesday, December 6th—Morning Session.*

**The Surgery of Biliary Calculi.**—Dr. W. D. Haggard, of Nashville, Tenn., contributed this paper. He spoke of the frequent findings of gall stones (ten per cent.) in the abdominal cavity, but said their unsuspected existence was not a valid contraindication to operation in cases which, owing to certain complications, menaced well-being and perhaps life itself. After enumerating the usually assigned causes of gall stones, he emphasized the undetermined probability of infection. The continuous pain in inflammatory and suppurative conditions of the biliary passages was contrasted with the intermittent and paroxysmal pain from biliary concretions. In connection with the diagnosis, the fact that jaundice was not essentially a sign of gall stones was emphasized, and waiting for icterus as an evidence of their existence was hurtful. The relatively small number of operations, compared with the frequency of the disease, indicated that the gall stones were either overlooked, or failed to give rise to serious trouble, or that the symptoms were taken for other diseases. The speaker quoted from Robson the indications for operation. The various incisions were described, and the operations of cholecystotomy, cholecystendesis, modified cholecystotomy (without suture), and cholecystectomy were discussed. He said that the surgery of the gall bladder was almost perfected, but the management of calculi in the ducts by various methods was yet unsettled. The various operations on the ducts were discussed. He reported the following case of cholocholecystostomy for chronic catarrhal cholangitis with gall stones:

B. J. G——, white, male, aged twenty-seven years. He had his first severe attack of biliary colic attended with tenderness and jaundice in February, 1897. He had had a severe and a light attack of hepatic colic some weeks before. He was operated on the day after he was taken with the severe attack, by Dr. J. F. W. Ross, of Toronto. A number of stones were removed; a fistula was made, and a drainage tube kept in for two weeks. The fistula remained open until June, 1897, when Dr. Ross closed it by suture, and the man, who had been in bed the whole of four months, was up in a week. In November, 1897, he again had a number of attacks of colic and jaundice, which kept up intermittently until March, 1898, when Dr. L. McLane Tiffany, of Baltimore, opened the gall bladder, but finding no stones he closed it by immediate suture, fixing it to the abdominal wall, and closing the incision throughout. In June of the same year, while still in the hospital, he was again seized with attacks of colic and transient jaundice, which, in the absence of Dr. Tiffany in Europe, induced his assistant, Dr. I. R. Trimble, again to open the gall bladder for exploration. Dr. Trimble found no stones, and thought he had succeeded in passing a rubber catheter through the cystic duct, and thence into the duodenum. The gall bladder was sutured and attached to the abdominal incision, which was closed by buried and superficial silkworm-gut sutures. On July 3d, the man had received a blow on the head with a piece of wood in the hands of a drunken assailant, which resulted in a fracture of the skull, which was elevated by Dr. Robert Pillow, of Columbia, Tenn. In August, 1899, fourteen months after the third gall-bladder operation, the pain and colic returned, and were rather frequent and more severe than ever before. On October 1st he had a spell that lasted four days, and could obtain no relief from anything. He came to see Dr. Haggard in Nashville, and while there had one of the worst attacks of biliary colic the doctor had ever seen. He gave the patient two and three-quarter grains of mor-

phine hypodermically in less than three hours, without any appreciable effect on the agonizing pain. The patient was not accustomed to taking morphine, and one-eighth grain after the operation had a very happy and full effect. On November 12, 1899, in the presence of jaundice, which had existed for two months, Dr. Haggard made an exploratory operation through the old scar, parallel with the ribs. As the gall bladder was attached to the parietes it was opened, and a black, tarry fluid was found therein, and one single, large gall stone, soft and perfectly black and somewhat larger than a cherry-stone, together with some smaller crystal-like stones. An effort was made to catheterize the ducts, as had been reported to have been done before without success. The gall bladder was irrigated and packed with gauze temporarily. It was then dissected from the parietes below, and a careful palpation of the ducts was made, but no other stones could be detected. The adhesions were considerable, as the result of so many previous operations and such long-continued inflammatory trouble, and the gall bladder was much contracted. Kelly, Senn, and Murphy had all advised a cholecystectomy, but after no calculus obstruction had been found to account for the recent colic and existing jaundice, he concluded it must be a chronic catarrhal cholangitis with inflammatory obstruction that came and went. He therefore deemed it unwise to do a cholecystectomy and decided to do a cholecysenterostomy. The duodenum, however, was so matted with adhesions, and the gall bladder was contracted to such an extent, that he did not think he could make the anastomosis with safety. He therefore utilized the hepatic flexure, and made a Murphy-button anastomosis with gauze drainage. There was no untoward symptom; a little bile came out after the gauze, when it was removed on the third day, but none thereafter; the drainage tract closed quickly. The jaundice faded, the urine cleared up, and the patient had two normal bowel actions a day, whereas he had previously been taking purgatives daily. He went home at the end of two weeks with a clear complexion, and a gain in weight, and had had no trouble since, but the button had not passed. McGuire reports a button retained over a year in cholecystenterostomy, but Treves had never had one to remain in the gall bladder.

In the discussion, Dr. F. W. McRae, of Atlanta, narrated a case operated upon a few months ago in which a diagnosis of cholecystitis was made. At the operation an unusual condition of affairs was found. Instead of a distended gall bladder, he found enlargement of the liver, with great distention of a cavity in this organ, hard and nodular to the feel, and occupying this cavity and some small pockets in various directions in the liver were fifty-eight stones, which he exhibited. The adhesions were extensive, but no pus was found.

Dr. J. G. Earnest, of Atlanta, directed attention to the symptom jaundice, saying that it did not appear unless there was obstruction of the common duct. Simple obstruction of the cystic duct did not necessarily produce jaundice. In two or three cases in which he had found the gall bladder filled with inspissated mucus and complete obstruction of the cystic duct, but no obstruction of the common duct, there was no jaundice, while in other instances of common-duct obstruction jaundice was present.

Dr. Hugh M. Taylor, of Richmond, Va., recalled a case which was diagnosticated at first as cholecystitis. The patient had been jaundiced for six weeks. The abdomen was opened, and on incising the gall bladder and removing a stone from it he found no obstruction of either the cystic or common duct. He did a cholecystostomy, and drained the gall bladder, but the patient did not recover. Two months later he reopened the abdomen, and, after a very careful examination, found malignant disease of the head of the pancreas sufficient to press upon the common duct and produce jaundice.

Dr. Manning Simons, of Charleston, S. C., reported a case in which he removed the whole gall bladder, and said that after a careful search of the literature at his command he could find only twenty cases. The tumor in his case presented just below the ninth rib as large as a goose egg. An exploratory operation was made, and the tumor was found to be the gall bladder. The gall bladder was removed because its walls were greatly thickened and pus had disseminated itself throughout its walls. He believed that if the gall bladder had not been removed at that time, and promptly, there would have been extravasation of pus into the abdominal cavity. Three gall stones were found. There was very little jaundice present.

Dr. A. M. Cartledge, of Louisville, spoke of the cholæmic cases, and said that in the use of the decinormal saline solution, employed either subcutaneously or per rectum, for ten days, two weeks, or in bad cases three weeks, before operative interference, surgeons had one of the most valuable means of overcoming cholæmia in patients with gall stones.

The paper was further discussed by Drs. Lewis S. McMurtry, J. Wesley Bovée, and George S. Brown.

**Inflammation of Meckel's Diverticulum with Resulting Gangrene of the Intestine Simulating Appendicitis.**—Dr. William P. Nicholson, of Atlanta, read this paper. He said that the pathological conditions arising from the diverticulum have been in most cases due to portions of the intestine being entrapped within the encircling cord when the diverticulum had existed in this form; while in some instances there had been an acute inflammation of the pervious tube that had caused adhesions and resulting obstruction. Again, the inflammation seemed to have extended to the intestinal tube, causing paresis of the bowel, especially simulating the later stages of appendicitis. In a few cases the symptoms and signs had been so much like inflammation of the appendix that a diagnosis had not been possible. The author reported an interesting and instructive case, and mentioned briefly other cases he had found in consulting the literature. He also reported a case of successful implantation of an artificial testicle.

**Two Cases of Intraligamentous Cysts.**—Dr. T. J. Crofford, of Memphis, reported the following:

Case I.—Miss T——, aged fifty years, presented herself with an abdominal tumor July 1, 1899. A few days later the abdomen was opened. The tumor was found to be an intraligamentous cyst. Both ovarian arteries were ligated; the uterine artery was ligated upon the healthy side at as low a level as the internal os. The uterus was cut across; the uterine artery was secured upon the tumor side, and the enucleation of the tumor proceeded with. The loss of blood was considerable, although the enucleation was done rapidly. Several arteries in the broad ligament required ligation, and one or two deep down in the pelvis needed to be secured before hemorrhage was under control. The cavity was obliterated as much as possible by suturing together the two layers of the ligament. The woman recovered.

Case II.—Mrs. S——, aged forty-two years, presented herself with an abdominal tumor October 31, 1899. During the month of June last she experienced an attack of acute peritonitis which came near terminating her life. The acuteness of the attack subsided, but a chronic peritonitis had existed ever since. Abdominal section was made November 6th. There were found two tumors, one on each side, developed between the layers of the broad ligaments. The ovarian arteries were secured near the brim of the pelvis.

The tumors, which were not of very large size, were separated from the uterus as far down as the operator dared, and the uterine arteries were secured as low as possible after the cysts were emptied. The hemorrhage was alarming at every attempt at enucleation upon all sides. The larger vessels in the broad ligaments and walls of the cysts, several in number, were therefore ligated. The upper portion of the sacs was trimmed off and covered with peritoneum. After the oozing had stopped the abdomen was closed without drainage. The patient had had an uninterrupted convalescence and had returned to her home.

The essayist said that Dr. Rufus B. Hall, of Cincinnati, had proposed the method of ligating both ovarian arteries and the uterine artery on the healthy side. The uterus was next amputated on a level with the internal os; the uterine artery on the tumor side was not secured, when he could peel out the cyst from between the layers of the broad ligament with a bloodless result. He said that while he did not wish to detract from the merits of this achievement, yet the method was not to be implicitly relied upon, as it would not control hemorrhage in all cases to a safe degree; in some instances there would be found other vessels requiring ligation before the hemorrhage could be controlled within the bounds of safety. Some tumors of the broad ligament could be peeled out without hemorrhage; others would be attended with considerable loss of blood.

**President's Address.**—This was delivered by Dr. Joseph Taber Johnson, of Washington, D. C. He touched on general subjects pertaining to the work and growth of the association. He said the southern part of our country had furnished many noted surgeons and gynæcologists to the medical profession; hence the name of the association derived greater appropriateness and significance from this fact. He referred to Drs. McDowell, Eve, Dudley, Sims, Thomas, Battey, and Emmet. The best gynæcologists were now the best surgeons as far as they went. In abdominal, pelvic, and genital surgery, few general surgeons equalled and none surpassed them. Their field of work was more narrow, but none the less perfect and important on that account. While many gynæcologists might take exception to such an absorption of their specialty, the gradual expansion of their work to the female pelvis gave the important argument for such an occurrence in the not distant future. It is not difficult to remember when gynæcology was limited altogether to vaginal and pelvic work. Now, there were very few gynæcologists who were not operating upon any tumor between the diaphragm and the vulva. The gynæcologists attacked ulcers and abscesses of the stomach, and anastomosed that organ with the intestine. They did all the surgery of the ureter and kidney, the liver and gall bladder, of the intestines, the spleen, and the pancreas. They operated for appendicitis and for all the varieties of hernia, and did the surgery of the bladder, the rectum, and the mammary gland.

There was no afternoon session on the second day. The members and guests took the steamer *Warren* and rode to the sugar plantation Stanton, owned by Milliken and Ruttledge, and inspected it.

---

*Second Day—Evening Session.*

**Experience in Operations for Typhoid Perforation.**—Dr. Hugh M. Taylor, of Richmond, Va., read this paper. He said it was claimed that one-third of the deaths from typhoid fever were due to perforation. Typhoid perforation was credited with a mortality of 16,660 each year in the United States. The specialist in surgery appreciated what surgery could do and had done in the treatment of typhoid perforations. The general practitioner, into whose hands these cases usually first fell, was not so well informed, and he believed the association should express itself in no uncertain sound. It was claimed, too, that one-fifth of the deaths from typhoid fever were due to hemorrhage. This being so, it would seem just as unsurgical to let a typhoid patient die without an effort to save his life as it would be in the case of profuse hemorrhage from a gastric or duodenal ulcer, or even a ruptured tubal gestation. The author reported five cases, with one recovery from operation. He said less than two hundred cases had now been operated upon. When one recalled the thousands of cases annually occurring, the need for co-operative study was apparent. Nothing short of a moribund condition of the patient should warrant surgeons in abandoning a case as hopeless. The key to success was early operation. More than one-fourth of the cases operated on had been saved by early surgical intervention. He believed that surgeons should be able to save more than $33\frac{1}{3}$ per cent. by a timely operation.

Dr. F. W. McRae, of Atlanta, reported some interesting cases of abdominal surgery. The first case was one in which he operated for a pancreatic cyst; the second for hepatic calculi; the third for fecal fistulæ; and in the fourth case he did a combined appendectomy and nephrorrhaphy.

**Litholapaxy.**—Dr. George S. Brown, of Birmingham, Ala., read a paper with this title. A very limited experience with the operation of litholapaxy had led him to believe that it was being unwisely, although not altogether unreasonably, neglected. The most important cause, perhaps, for this neglect was that cutting operations, particularly the suprapubic, were very easy to do, and the results were very satisfactory. The author quoted the statistics of the different methods of operating for stone in the bladder, and reported cases in which he had resorted to litholapaxy with good results. He believed that the majority of stones met with in practice in this country could be removed with the lithotrite in the hands of an ordinarily careful surgeon, and that, while it was not an operation to be undertaken by the general practitioner, no operating-room should be without the instrument; that the suffering and time spent in bed were almost entirely eliminated, and that the mortality was very much lower than that for either of the cutting operations.

*Third Day—Thursday, December 7th—Morning Session.*

Dr. E. D. Fenner, of New Orleans, reported fifteen cases of spinal injuries, treated at the Louisiana Charity Hospital.

Dr. George H. Noble, of Atlanta, described the modification of an operation for cystocele. He also reported a case of seventeen years' congenital nocturnal incontinence of urine, and one of pregnancy in a uterus bicornus.

Dr. I. L. Watkins, of Montgomery, Ala., presented a paper on "The Treatment of Retro-Displacements of the Uterus."

The following officers were elected: *President*, Dr. A. M. Cartledge, Louisville, Ky.; *Vice-Presidents*, Dr. Manning Simons, of Charleston, S. C., and Dr. W. P. Nicholson, of Atlanta, Ga.; *Secretary*, Dr. W. E. B. Davis, of Birmingham, Ala.; *Treasurer*, Dr. W. D. Haggard, Jr., of Nashville, Tenn.

Atlanta, Ga., was selected as the place for holding the next meeting in 1900. Time, the second Tuesday in November.

## NEW YORK ACADEMY OF MEDICINE.

### SECTION ON MEDICINE.

*Stated Meeting, November 21, 1899.*

JOHN H. HUDDLESTON, M.D., CHAIRMAN PRO TEM.

**Diabète Bronzé and the Pathogenesis of Diabetes Mellitus.**—DR. HENRY W. BERG read a paper with this title, and presented a photograph of a patient with bronzed diabetes and exophthalmic goitre, the patient herself being too weak to be present (see page 881).

**The Pathology of Diabetes Still a Mystery.**—DR. WILLIAM H. THOMSON said that in pernicious anæmia there was an abundant deposit of iron in the liver, but it was deposited only in the portal capillaries, showing that there was something peculiar about the portal blood. In that disease the urine contained from one hundred and fifty to two hundred per cent. more iron than in any other disease. He was disposed to accept the theory that this deposition of iron was brought about by a form of toxæmia having its origin in the intestinal tract. He believed the cirrhosis of diabète bronzé was the result of the action of an irritant in the portal circulation, and that this also accounted for the deposit of iron in the liver, and explained also the bronzing of the skin. He agreed with the reader of the paper that this bronzing was quite distinct from that observed in Addison's disease. The pathology of diabetes had always been most elusive, as was well shown by the fact that now Pavy renounced the theory of the glycogenic function of the liver and claimed that the muscles possessed the glycogenic function just as much as the liver. Temporary glycosuria might be explained by a nervous irritation, but diabetes being a persistent glycosuria could not be regarded as the result of any nervous irritation.

DR. MARY PUTNAM JACOBI said that there must be many causes of diabetes for the reason that there were many conditions affecting the production and excretion of sugar. However, there were three fundamental types, viz., (1) Diabetes of nervous origin; (2) the ordinary hepatic diabetes associated with increased production of sugar in the liver; (3) the pancreatic diabetes. There seemed to be a difference of opinion among the French themselves as to whether bronzed diabetes was a distinct entity or whether the hypertrophic cirrhosis and the pigmentation were merely complications grafted upon ordinary diabetes. It was rather singular that in the descriptions of this comparatively new and extraordinary disease very little had been said about the pancreas. She did not think there was any connection between the exophthalmic goitre and the bronzed diabetes; they were merely coexistent disorders.

**No Previous Case in Woman.**—DR. S. J. MELTZER said that the report of the first case of bronzed diabetes in this country had been published in the *Journal of Experimental Medicine* last June or July, and Dr. Osler had such a case under observation. He had been rather surprised that the author of the paper had looked upon his case as presenting two disorders—an exophthalmic goitre and bronzed diabetes—when it was well known that exophthalmic goitre was associated with pigmentation in about twelve per cent. of the cases, and was not uncommonly followed by ordinary diabetes. He personally preferred to call this disorder general hæmochromatosis. He was disposed to look upon the case under discussion as one of exophthalmic goitre and not of bronzed diabetes, and he would say, in this connection, that if this was a true case of bronzed diabetes it was the first one that had been observed in a woman. That the diagnosis of general hæmochromatosis was most difficult to make had been clearly shown at a recent discussion of this subject by the Association of American Physicians and Surgeons.

**Graves' Disease Seldom Associated with Diabetes.**—DR. ALFRED HEVER said that any effort to analyze the many facts regarding the etiology of diabetes and bring order out of the mass of evidence that had accumulated in this mysterious field was deserving of praise. It was the first time that he had seen this combination of hypertrophic cirrhosis of the liver, exophthalmic goitre, and diabetes, and the case certainly simulated bronzed diabetes very closely. His own opinion was that Graves' disease and diabetes seldom occurred together, and additional weight had been given to this notion by the few cases which the author of this paper had been able to collect.

**The Diabetes a Secondary Feature.**—DR. N. E. BRILL agreed with the last speaker in the view of the case. The latest writers on this subject, he said, had taken the view that this was a general dissolution of the hæmoglobin primarily, and not a diabetes at first. The deposition of the pigment was apt to cause degeneration and death of the liver cells, with the result that an interstitial inflammation was set up. This inflammation, in turn, set up the hypertrophic cirrhosis. Of the twenty-four cases cited in literature, in seventeen the pancreas had been examined. In all of these cases there had been a chronic interstitial pancreatitis. In all the glycosuria had been a late occurrence, and in the case reported by Opie glycosuria had not appeared up to the time of the death of the patient from an intercurrent disease—typhoid fever. In all of the cases of bronzed diabetes it had been stated that the deposition of pigment was general and diffused, whereas in the case of Dr. Berg there were large areas entirely free from pigment. He had had an opportunity of seeing this patient, but had been unable to detect enlargement of the liver, and there had certainly been no enlargement of the spleen, although splenic enlargement had been noted in the majority of the cases reported. At the time of his examination ascites had not been present. He was, therefore, of the opinion that this was a case of diabetes associated with Basedow's disease, and that the pigmentation of the skin was of the nature of chloasma.

**The Diagnosis Disputed.**—DR. M. MANGES said that shortly before this woman had entered his hospital service he had had a case in which there had been diabetes, pigmentation, and hypertrophic cirrhosis, and yet at the autopsy the case had been proved to be one of Addison's disease with glycosuria. There had also been a carcinoma primary in the pancreas, with secondary involvement of the adrenals and liver. He had, therefore, looked with great suspicion upon the present case, and had called in the consulting dermatologist, Dr. Lustgarten. The photograph exhibited this evening did not show well the nature of the pigmentation, which was really best described as a diffused chloasma. There was only one part of this patient that showed a true bronzing, *i.e.*, one buttock. He had watched the case for about two months, and had come to the conclusion that it was not one of bronzed diabetes. The woman had then passed over to the service of Dr. Rudisch, who had coincided with him in the opinion that it was not a case of bronzed diabetes. The autopsy alone could positively settle the diagnosis. While the case had been under his care there had been no ascites and no enlargement of the spleen, and no turgescence of the veins of the abdominal wall. There had been some enlargement of the liver, the organ extending from the sixth rib down to two fingers' breadth below the border of the ribs. Moreover, this enlargement of the liver had not been uniform, and had been more marked in the left lobe.

In his hospital service pigmentation was very commonly observed, and this case certainly seemed to come under the head of chloasma cachecticorum, as had been stated by Dr. Lustgarten. Another interesting fact in connection with this case was that emaciation had not been noted in the other reported cases of bronzed diabetes.

**Deductions from Experiments on Animals.**—Dr. A. Mayer said that he believed Dr. Berg's diagnosis was correct. If a saturated solution of indigo-carmine was injected into the jugular vein of a live animal the bile capillaries would be found, a few hours later, filled with crystals of indigo-carmine. Not only that, but the glycogen stored up in the liver would disappear. He had noted this so often in experimental work that he was sure that it was a fact. If indigo-carmine would do this in the liver cell, it seemed to him probable that a pigment deposited in the liver cell would do the same thing. Anything which would irritate the liver cell might produce a glycosuria by interfering with the storing up of glycogen.

**Bronzed Diabetes not an Entity.**—Dr. Berg closed the discussion. He said that he did not look upon diabète bronzé as a clinical entity, but a collection of symptoms, all of which could be explained by the dilution of the blood with a solution of sugar. It was important to remember that while the exophthalmic goitre had developed nine years ago, the pigmentation had not appeared until two years ago. There were white atrophic areas of the skin interspersed with dark brown spots on the face. Regarding emaciation he would say that in all the cases reported by the French emaciation had been present.

---

*Stated Meeting, December 7, 1899.*

William H. Thomson, M.D., President.

**The Wesley M. Carpenter Lecture: Researches on Infection by the Tonsils.**—Dr. Frederick A. Packard, of Philadelphia, delivered this lecture. He said that a more accurate title would be "Infection through the Tonsils, Especially in Connection with Acute Articular Rheumatism." He had been interested in this subject ever since he had been the registrar of the Pennsylvania Hospital. The constant shedding of the buccal epithelium of the mucous membrane, and the flushing of the cavity with saliva, constituted important obstacles to infection of the system with the many micro-organisms present in the mouth. In the area of the pharynx was found a group of lymphadenoid tissue, the ring of Waldeyer. In the higher animals the tonsils progressively approached the structure of these organs in the human subject. The tonsils should be looked upon as groups of lymphadenoid tissue. It was probable that one of the chief functions of the tonsils was the formation of leucocytes. The recesses of the mucous membrane covering the tonsil might serve the purpose of reservoirs in which the secretions might accumulate. Judging from analogy with other lymphoid tissues of the body, one could surmise that the tonsils exerted a protective influence. The absorbing power of the tonsils had received much attention from many investigators, and the tonsils had certainly been proved to absorb material from their free surfaces, as well as from their crypts. He personally looked upon the tonsil as lymphatic filters. That micro-organisms might pass through the tonsils had been shown by the finding of streptococci in the blood in a case of angina. The phenomena of acute tonsillitis were those of acute toxæmia. Inflammation of an area of similar extent in any other portion of the body would give no such great disturbance. Lymph nodes elsewhere served as a safeguard to the system, (1) by filtration, and (2) by weakening the virulence of the micro-organisms reaching them, and the tonsils probably acted as did other lymph nodes. This probable function of the tonsils should be borne in mind when the question of removing them was considered. Last May he had reported five cases of acute endocarditis following closely upon angina, in three of which the heart had been known to have been normal prior to the attack of angina. A most interesting experiment was the production of an endocarditis in a healthy rabbit by infection of the animal with streptococci obtained from the mouth of the experimenter. This experiment had been successfully performed. Dr. Packard said that he had been astonished at the number of cardiac cases coming with a history of one or more severe attacks of sore throat, and it was not at all uncommon to meet with cardiac disease in persons giving no history of rheumatism. Cases had been observed by him, and had been reported by others, in which dry pleurisy had developed in connection with angina. Of forty cases of cutaneous manifestations occurring in connection with angina, there were erythema nodosum in twenty-nine, purpuric eruptions in four, and erythema multiforme in two. Two cases were narrated to illustrate the connection of tonsillitis with chorea, and a historical sketch was given of bacteriological investigations bearing on the relation of angina to this disease, and, in general, to the infectious theory of chorea. Cases of acute yellow atrophy of the liver and of peritonitis had been reported as occurring in connection with tonsillitis. Palatal palsy was not extremely rare after angina, particularly after diphtheritic angina. Pyæmia as a result of tonsillitis was unusual, yet Wainwright had reported such a case, with death on the eighth day. Streptococci had been found in this man's blood. The greater malignancy of nasal diphtheria as compared with tonsillar diphtheria was to be explained by the fact that in true tonsillar diphtheria immediately beneath the seat of the infection was true lymphadenoid tissue, whereas in the nasal cavities this lymphatic protection was absent. Regarding the nature of rheumatism, the speaker said that a specific organism had not been found here, any more than had such a discovery been made in scarlatina, variola, and other diseases generally admitted to be infectious. The frequent absence of micro-organisms from the joint cavities in acute articular rheumatism had been explained on the theory that the arthritis of rheumatism was the result of the toxins and not of the bacteria. The view that rheumatism was a modified pyæmia had much in it that was attractive. If rheumatism was admitted to be an infectious disease, the point of entrance of the poison should receive consideration. The frequency of angina preceding rheumatism had been noted by many writers. In many of the fatal cases of rheumatism the tonsils revealed post-mortem evidence of abnormality, although they had appeared healthy during life.

**The Medical Profession in Italy.**—Italy contains 22,000 qualified practitioners, including 1,200 at Naples, 1,000 at Rome, and about 750 at Milan and Turin respectively. This gives a proportion of 1 in 1,400 for the country and about 1 in 550 for the large towns. "What is the condition of this class, and is there a future for physicians in Italy?" asks the *Gazzetta Lombarda*. In reply it points out that 9,000 have their bread assured by the Condotto, *i.e.*, are hired by communes or benevolent societies, about two-thirds having to treat all the inhabitants of a commune, and the remaining one-third the poor only. The salaries of the latter range between 1,000 to 2,000 lire (on a liberal exchange $200 to $400), while the former may get about twice as much.

## OUR LONDON LETTER.

(From our Special Correspondent.)

NEW MOVE IN MEDICAL POLITICS—ANTISTREPTOCOCCUS SERUM—OPEN-AIR TREATMENT OF TUBERCULOSIS—HULL EPIDEMIC—STRANGE BLUNDER OF A MEDICAL WITNESS—CONVICTION OF ABORTION GANG—LEICESTER'S CLIMB-DOWN.

LONDON, November 24, 1899.

WE are again in for a season of medical politics. Not that the tame proceedings at the College of Surgeons which I told you about will have any influence, nor that much good is anticipated from the meeting of the Medical Council which opens on Tuesday next. But a new departure has been taken on the initiative of several societies in the North of England. At the joint invitation of these societies the direct representatives in the Medical Council all three attended a conference at Newcastle on Wednesday evening and made rather lengthy speeches. Six societies took part in organizing the meeting, and about one hundred and sixty doctors attended the conference. Such a movement may or may not lead to important results. Much depends on the extent to which the precedent may be followed, and some of the speakers were animated by the hope that practitioners in various districts would organize similar meetings.

The constitution of the Medical Council was a prominent subject for the three representatives, and Mr. Horsley admitted that the quickest reform would be to give every holder of a diploma a vote for the body which conferred his qualification. This plan was proposed from the formation of the Council, though Mr. Horsley did not seem aware of the fact. His ideal would be for practitioners to vote in districts, but he felt that it could not be attained. He may comfort himself, for there is much to be said against such localization. Territorial distinctions have had their day. Mr. Horsley was to a certain extent on his defence for supporting the midwives bill of the British Medical Association. He feels sure that the women's influence will carry some bill through the House of Commons, and so adopts the bill he considers least injurious. This is hardly the policy one would expect from so fearless an advocate of professional rights, and I regret he has adopted it. But I cannot sympathize with those who accuse him of breaking his election pledges. The bill of the Association is admitted on all hands to be bad, though others may be worse. The Council of the Association has forced it forward in direct opposition to every general meeting. This is, you will say, scandalous. Alas! it is not the first time that this Council has perpetrated "a great betrayal" of the profession.

Mr. George Brown exposed again the conduct of the rulers of the corporations and wanted more direct representatives. Dr. Glover, too, wanted additions, but it is childish to expect that a number can be added to outvote the corporations.

The demand for a one-postal system was reiterated and is certainly less impracticable.

After the representatives had made their speeches some questions were asked and answered more or less fully, but there was not much time to spare for discussion, though the conference did not break up until 11 P.M.

I gave you a pretty full account of the discussion at our Obstetrical Society on antistreptococcic infection, thinking your readers would like to compare it with the report of your Gynæcological Society, which has attracted considerable attention on this side and confirms the views of many observers. A further contribution to the question was made on the next day at a sister society (the Harveian). Dr. Washbourn held that erysipelas, puerperal fever, septicæmia, etc., were manifestations of a single disease due to streptococcal infection, and that there were distinct varieties of the streptococcus which could be distinguished only by their behavior toward serum. As the serum seemed of great value in some cases but valueless in others which were apparently identical, he explained the different results by the different varieties of the streptococci present, and suggested that when the serum failed a second sample from a different source should be tried.

Dr. Dean also insisted on these differences, and said two streptococci of similar virulence might differ greatly in the ease with which the virulence could be increased by passage through rabbits. He also reported that an attempt was being made at the Jenner Institute to prepare a poly-virulent serum by using streptococci obtained from varying sources.

Dr. Goodall had tried the serum in malignant scarlet fever without benefit. Other speakers mentioned their experience, which was for the most part rather unsatisfactory. Dr. Ewart had seen in one case improvement after each injection, and ultimate recovery. But in this case the streptococcus had been found in the blood. The general impression is to reject as worthless all cases in which it has not been proved to be present. Again the question of mixed infections gave rise to differences of opinion. The indiscriminate use of this serum is certainly to be deprecated. Perhaps the more prevalent view in this country to a great extent coincides with that of the American report I have already referred to, and you will remember that at the British Medical meeting Dr. Spencer's report pointed to similar conclusions.

The open-air treatment of tuberculosis is now being discussed at the Medico-Chirurgical Society. Dr. Kingston Fowler opened the discussion, and was followed by Sir W. Broadbent, Professor Boyce, Dr. Burton-Fanning, Dr. Thurman, and Professor Clifford Allbutt. So far as it has gone the debate has turned largely on the construction and management of sanatoria, the importance of diet, exercise, temperature, climate, and general treatment; also whether the patients should be kept separate or together, and the maintenance of reasonable discipline. There were further strong expressions of opinion as to making sanatoria centres for research on tuberculosis.

Dr. Fowler insisted on a suggestion he had previously made, to substitute the term "pulmonary tuberculosis" for phthisis or consumption, and such diagnosis, he said, would be accompanied by an assurance that the disease often was arrested. It may, he thought, be doubted if intelligent patients would be deceived by a change of name, and it might be better to give them the assurance that consumption, as they will persist in calling it, may undergo arrest. He would, too, prefer the term "sanatorium treatment" to open-air, as fresh air is only one of several factors. Brehmer's system was stated by Dr. Fowler to consist in (1) residence in a sanatorium under constant medical supervision; (2) complete freedom from any excitement; (3) life in the open air; (4) rest during febrile periods; (5) methodical hill climbing as exercise when fever is absent; (6) abundant and varied diet, in which vegetables hold an important place; (7) hydrotherapeutic measures. Dr. Fowler did not regard any of the modifications of this system which had been proposed, as improvements. Hill climbing he said strengthened the muscular power of the heart, and a patient stuffed with food and kept at rest might become stout and flabby without arrest of his disease. The greater the amount of food taken, the less was

the significance of a gain in weight as evidence of arrest of the disease. Some establishments were really hotels rather than sanatoria. Nordrach should be the model. The number of patients in each sanatorium should be restricted to forty-five or fifty, so that the physician could supervise every one. The temperature should be taken in the rectum, where it might be 0.5° or 1° or even 2° above that of the mouth. The great object was to develop the resisting-power of the body by every means. They were dealing with pulmonary tuberculosis—not with catarrhal inflammation from "catching cold." Catarrh was no doubt an infectious malady, and patients under the open-air treatment did not catch it. Visitors to the Scotch hills could get wet through without taking cold.

Sir William Broadbent indorsed nearly everything advanced by the opener of the debate, but he held to the term "open-air" as the prime factor. Isolation was no doubt an important point in sanatorium treatment; so was the avoidance of all secondary infections—influenza being very disastrous. Sanatoria should be conducted on scientific lines and the commercial element excluded. He found the mouth temperature a sufficient guide. Feeding must be according to the needs of each patient—no hard-and-fast routine being adopted.

Professor Boyce dealt chiefly with the construction of sanatoria. Curiously, though Nordrach was so lauded in England, he had met with many German physicians who had never heard of it. He did not think it an ideal. The block system had more freedom of air, more homeliness, and was cheaper. Dr. Trudeau's at the Adirondacks was excellent. The rules should not be too Spartan. Well-equipped laboratories were essential.

Dr. Burton-Fanning said he had evolved a proper sanatorium after four and a half years' study. He said the treatment should be begun early, and then if continued long enough the patient would certainly recover, the first sign of improvement being in the weight and symptoms. He took temperatures in both mouth and rectum, and found after a short walk the rectal might be 0.5° above the oral, but would soon go down. As a rule there was very little difference between the two, but that was constant. An objection to rectal observation was that patients had to go to their rooms. In nervous patients the temperature ran up very rapidly.

Dr. Thurnam declared himself "an apostle of Nordrach." He saw no necessity for Liegehalle; the point was whether patients should be separated, and he thought, with due limitations, the fewer together the better for them. They should not get into groups. He preferred rectal temperatures as easiest to take and most sensitive, the range being wider but truer.

Professor Allbutt in visits to sanatoria had been struck by the difference between treatment by open air and by draughts. In pavilions on the H plan, the dining-room being north and south and the windows open, it became a portico and the wind blew through it as through a passage. In small bed-rooms, too, there were a lot of circular draughts. The result was "a lot of cold-catching." He admitted a cold was an infectious disease, but these catarrhs were extremely depressing. Camping out in the open was better than draughts. Patients, he was told, did not complain, but he had seen them with cyanotic faces and livid hands. In such states the vital powers must be depressed by draughts. The discipline was often most trying. Patients should be cheerful. If not allowed to read a book, which implied a little mental exercise, or to speak to a friend, the result would be enforced imbecility. He agreed with the opener as to increase of weight in relation to exercise. High feeding required discretion. Cure was a relative term. He would restrict it to cases in which patients had returned to their ordinary work for a year and remained well all the time. He indorsed Professor Boyce's remarks on the necessity of research.

The debate was then adjourned.

An extraordinary proceeding has taken place at Hull. A sub-committee resolved to withhold all information about the smallpox epidemic even from the town council, including the members of the health committee. At the meeting of the full health committee on Wednesday, the resolution of the sub-committee was set aside, and it was agreed to publish the facts. The returns show 210 persons in hospital on Tuesday. The fresh cases reported were: On Sunday 17, Monday 9, Tuesday 5, Wednesday 3. The number of cases since the beginning of the outbreak is 552. The deaths have been 13.4 per cent.

A strange blunder seems to have been made by a medical witness who testified that the death of a man was the result of a broken neck. This led to the arrest of his wife on a charge of murder. Further examination by an expert for the Home Office showed that there was no trace of a broken neck, and the man had died of acute pneumonia. The judge at the assizes ordered the release of the accused, commented severely on the unaccountable blunder, and told the medical witness he ought to make every compensation he could to the victim of his carelessness, who had had a narrow escape from execution for a crime never committed.

The police seem at last to have succeeded in breaking up the abortion business carried on as Mme. Frain's Medical Institute. They have secured the conviction of five persons for conspiracy to incite women to administer to themselves noxious things. The evidence showed that the business was extensive and profitable. After the prosecution was begun the convicts returned money to over thirteen hundred applicants for the remedies. Mr. Justice Darling gave a significant warning to the newspapers which insert such advertisements. The learned judge distinctly said that they were liable and the proprietors might be indicted for conspiracy too. Now let the police carry their war into the newspaper offices.

The courage of the Leicester Guardians, who so earnestly protested their desire to be imprisoned as antivaccinators, has failed them in presence of the rule *nisi* for an attachment. They have now judiciously resolved, by twenty-five to nineteen, to appoint a vaccination officer in obedience to the court.

The Luton Guardians, who imitated those of Leicester, had better carry their imitation as far and climb down without more ado. It is to be hoped that in all cases of such defiance of the law the would-be martyrs may be mulcted in costs as individuals, and that the rate-payers may not be required to pay.

## UNWARRANTED ARRESTS OF PHYSICIANS.

To the Editor of the Medical Record.

Sir: Your editorial, "An Unpardonable Indignity," in your issue of November 4, 1899, was most admirable, and I wish to offer you my hearty thanks for it. When such an influential journal as yours, and the leaders of the medical profession take such a deep interest in the matter, it gives great promise that we may succeed in having the law so amended that it will be safe for honorable men to practise general medicine in this city and State.

The letters of several eminent physicians which I enclose, and which I have permission to publish, refer to the subject that prompted your able editorial above mentioned. That is, the recent unwarranted arrest of

two physicians, who, out of charity, attended a poor woman who had been ill and neglected for two weeks. To give her the best chance to recover, one of the physicians sent her to Bellevue Hospital, where a positive diagnosis was not made. On October 18, 1899, she died. After her death, by the merest accident Coroner's Physician Donlin discovered that at some time in the past she had aborted, and he claims to have found one or two slight "contusions" that caused him to believe that a criminal operation had been performed. He claims that the woman had been pregnant six weeks, and that he found a "necrotic mass in the fundus uteri apparently placental." He at once handed the case over to the police for investigation. Their investigation consisted in ascertaining what physicians had ever attended the woman, and that only.

The physicians who were arrested had no difficulty in proving that, if there had been a criminal operation performed, they could have had nothing whatever to do with it, and the coroner's jury, after a very few minutes' deliberation, brought in this verdict: "That "the said Nora Selz came to her death on the 18th of October, 1899, at Bellevue Hospital, by asthenia from septicæmia, following criminal abortion at about sixth week of utero-gestation, induced by some person or persons unknown to the jury, and we exonerate Drs. Harry R. Purdy and Otto Maier from all responsibility and blame." HARRY R. PURDY.

149 LEXINGTON AVENUE, December 7, 1899.

DEAR DOCTOR PURDY: I have read the testimony in the case of Nora Selz. I am convinced by the perusal that gross injustice was done to Dr. Harry R. Purdy and to Dr. Otto Maier by the action of Police Captain John Delaney. The testimony distinctly shows that the woman was already ill when these physicians were called to see her. It also shows that they were called in by her neighbors because she was ill. This evidence is not such as entitled the police captain to regard these physicians with suspicion as the person or persons who had brought about the disease. The police captain has access to physicians, as the police surgeons or deputy coroners. These he should, in my judgment, have consulted before resorting to such a measure as the arrest of reputable physicians for the production of a crime. A police captain, in my opinion, should have sufficient knowledge, judgment, and discretion as would have prevented him from making such a mistake as this was. It demonstrates to me that he was not possessed of such desire to avoid the injury of the innocent as should be possessed by one intrusted with the responsibility of the office he holds. The system which is productive of such a case as this needs revision.

Yours very truly,
E. G. JANEWAY.

36 WEST FORTIETH STREET, December 1, 1899.

DEAR DOCTOR PURDY: My perusal of the papers which you have submitted to me convinces me not only that you were subjected to most outrageous treatment, but that the medical profession must take up your case as its own without delay. Not a physician in practice, however reputable and conscientious, is safe in New York City if he can be dealt with by the presumed law officers of the city as you were, arrested on such a criminal charge and with the effect of being published throughout the land by the daily press as an abortionist. No other business, calling, or profession is exposed to such ruinous perils as ours, if such experiences are possible, besides the damage to personal reputation which to many would outweigh all pecuniary loss.

Thorough legal remedies must be provided for, to insure the safety of reputable medical men from such injustice, and it is here that, in my opinion, care should be taken that all steps toward that end should be so devised as to secure the desired result. The one medical organization which is recognized by the law of the State of New York as entitled to take cognizance of and act upon all questions pertaining to the legal status of medical practitioners, is the County Medical Society. Any other medical societies could not appear as such or by their representatives in any court, except as private parties or individuals, but the New York County Medical Society can compel a hearing before any judge. What the other organizations should do, however, is to have the question brought before them at one of their stated meetings, for an expression of opinion on it, to be made a matter of record. The by-laws of the Academy of Medicine unfortunately enjoin that no question of a public nature, not scientific, can be acted on at any meeting unless due notice of the matter be given at a previous stated meeting. If any member of the Academy would give notice of such a motion accordingly, I have no doubt that it would be entertained; but meantime, as an individual, I would be glad to co-operate with any friends of yours to have the question discussed and proper action taken on the first opportunity at the County Medical Society.

Yours sincerely,
W. H. THOMSON.

23 EAST FORTY-SEVENTH STREET, December 1, 1899.

*Dr. H. R. Purdy.*

DEAR DOCTOR: Yesterday, on my return from the hospital, I found awaiting my examination the papers you so kindly forwarded to me. Without attempting any other work I promptly read through the evidence in question, and I am forcibly impressed with the fact that there is great need of wiser and more considerate discrimination on the part of public officials, or that their powers be diminished to correspond with the lack of wisdom displayed in the exercise of their duties.

The question is a somewhat perplexing one. Just how to accomplish the purpose is much more easily arrived at than carried into effect. I am disposed to feel it would be better for you, at your earliest convenience, to run in and talk with me about the proposition you have in view, and it is not at all improbable that we may mutually instruct and possibly support each other in forming final conclusions.

Yours very sincerely,
JOSEPH D. BRYANT.

54 WEST THIRTY-SIXTH STREET, December 1, 1899.

*Dr. Harry R. Purdy.*

DEAR DOCTOR: Permit me to extend to you my hearty congratulations upon your "vindication." The wretched farce which resulted in your arrest and appearance at a coroner's court needs no comment. That a reputable physician engaged in a work of charity should be insulted and injured as you have been, is a reproach to our laws, or, rather, an example of our need of laws. I have investigated the case, and not only am impressed with the absolute injustice of arresting you upon such flimsy evidence, for there was not only nothing in the woman's symptoms to create the suspicion that she had aborted, but an inspection of the post-mortem examination and other information that has come to me makes me doubt the existence of any conclusive evidence that she had lately miscarried.

Very truly yours,
ALLAN MCLANE HAMILTON.

44 EAST TWENTY-NINTH STREET, December 3, 1899.

---

**Functional Impotence.**—Ligate the dorsal vein of the penis under cocaine.—WILEY BROOME, *Med. Rev.*

# Medical Items.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 9, 1899:

| | Cases. | Deaths. |
|---|---|---|
| Tuberculosis | 144 | 138 |
| Typhoid fever | 66 | 20 |
| Scarlet fever | 138 | 6 |
| Measles | 337 | 11 |
| Diphtheria | 255 | 40 |
| Laryngeal diphtheria (croup) | 15 | 10 |
| Cerebro-spinal meningitis | 0 | 4 |
| Chicken-pox | 20 | 0 |

**The Dum Dum Bullet.**—Professor Bruns, at the German Congress, described these projectiles. He said that they were originally coated with nickel, but as it was found that the enemy's soldiers when wounded were not invariably disabled, the nickel coating was filed away from the top of the bullet. In fact, the nickel covering enabled the bullet to pass through the body, making only a relatively small wound, but when this covering was removed from the top the lead was flattened out as soon as it struck the body, by which flattening the remainder of the covering was burst open in an explosion-like way, inflicting wounds of an astonishingly severe character.

**Climatic Treatment of Tuberculosis.**—The treatment of tuberculosis by climate, says Dr. W. Howship Dickinson, is nothing new. For over one hundred years scrofula or tuberculosis not of the lung has been treated at Margate, England, by exposure to the air of the North Foreland, with a success which has not been attained elsewhere. Pulmonary tubercle has also long been dealt with climatically, but with a less bold appeal to fresh air. The desiderata for this condition were, in the minds of our predecessors, warmth and equability. This was distinctly formulated by "the great Thomas Young," and represented the practice of 1815 and many subsequent years. Consumptives were accordingly sent to low-lying and sheltered places on the seacoast, and were crowded into hospitals in towns where, if some of the desired conditions were present, the most important were assuredly wanting. Protection from catarrh is essential; here we are at one with those who preceded us; but we recognize what they did not—the paramount influence of virgin air. High altitudes and ocean expanses, together with an open-air life, even though somewhat careless, accomplish what was not attained when the chief aim was protection from cold, and the invalid was surrounded with precautions lest the winds of heaven visit his face too roughly. Now for tuberculosis of every kind we make alliance with the powers of the air, whether on the historic North Foreland or where the north Atlantic pulverizes itself on the Cornish cliffs, or on the lofty levels of South Africa, where the invalid may walk in warmth and comfort at an altitude greater than the summits of Snowdon and Ben Nevis.—*Public Opinion.*

**Eels as Water Purifiers.**—Professor Sobrero, of Turin, has recently suggested that eels should be used as purifiers of water. All that one has to do is to put two or three eels, not very big but lively, into the domestic cistern. The fish devour with marvellous appetite everything which the water may chance to contain in the way of animalcules, infusoria, bird droppings from the roof, vegetable matter of any kind; nothing comes amiss to them. When the eels have fulfilled their mission they can be eaten *à la tartare*, or they can be kept for further use as purifiers of the water supply. Such a method of fattening eels for the family table may not commend itself to the average British stomach, though these fish eat worse things in their ordinary haunts than they are likely to find in a cistern, even within the area of distribution of a London company. But as water purifiers a useful sphere of action might be found for them in reservoirs as well as in cisterns.—*British Medical Journal.*

**The Open-Air Treatment of Consumption in a London Hospital.**—In the London Hospital for Consumption the basis of treatment is rest in the open air, graduated exercise, and good feeding. No window in the open-air wards is ever closed, and during the cold weather the consumptive patients are kept warm with extra clothing and artificial heat. It is encouraging to note that practically all the early cases and seventy per cent. of all cases improve considerably under the open-air system.

**Very Old Fogies.**—More people over one hundred years old are found in mild climates than in the higher latitudes. According to the last census of the German empire, of a population of 555,000,000 only 78 have passed the hundredth year. France with a population of 40,000,000 has 213 centenarians. In England there are 146; in Ireland 578, and in Scotland 46. Sweden has 10, and Norway 23; Belgium 5; Denmark 2; Switzerland none. Spain with a population of 18,000,000 has 401 persons over one hundred years of age. Of the 2,250,000 inhabitants of Servia, 575 have passed the century mark. It is said that the oldest person living is Bruno Cotrim, born in Africa and now living in Rio de Janeiro. He is 150 years old. A coachman in Moscow has lived for 140 years. —*Indian Medical Record.*

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended December 8, 1899:

### AN ACCOUNT OF SOME PERSONAL WORK ON THE MOSQUITO-MALARIA THEORY, WITH REMARKS UPON THE PRESENT STATE OF THE INVESTIGATION.[1]

BY WILLIAM N. BERKELEY, A.B., M.D.,

NEW YORK,

ATTENDING PHYSICIAN AT THE GOOD SAMARITAN DISPENSARY; ASSISTANT IN MEDICINE, UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

SINCE the publication in the *British Medical Journal* for December 18, 1897, of Surgeon-Major Ronald Ross's epoch-making discovery of pigmented malarial organisms in the stomach-wall of the "dapple-winged mosquito," the mosquito-malaria theory has made rapid advances. While many important collateral points remain to be determined, the theory now rests in essentials upon a rigidly experimental and scientific basis.

In brief, it has been demonstrated by competent observers in India, Italy, and Africa that certain species of Anopheles, when fed upon malarial blood and kept at a favorable temperature, show in the stomach-wall during the next five to seven days a series of uniform and characteristic phenomena. There first appears in the meshes of the gastric muscle fibre, outside of the secreting epithelium, a small roundish pigmented body 6–8 $\mu$ in diameter. This body (zygote) is usually demonstrable by the end of the second day after inoculation. Fig. 1[2] illustrates a generally similar process in the stomach-wall of Culex pipiens fed on a bird infected with avian malaria (Proteosoma). The germ in its new site grows fast. By the end of the fifth day it measures 50 $\mu$ and more, and has a distinct wall or capsule (Fig. 2). Within many of the capsules (or "coccidia") a succession of elaborate reproductive changes occurs. On the seventh or eighth day (the exact time varying with conditions of temperature) the capsules rupture, and discharge into the cœlomic or general body cavity of the insect swarms of minute, straight, or slightly curved filaments (zygotoblasts) 12–16 $\mu$ in length and provided with terminal flagella. These filaments—first called by Ross "germinal rods," and in the German literature *Sporozoiten* (Nuttall) and *Sichelkeime* (Koch)—spread throughout the circulation of the insect and settle in great numbers in the cells of the poison-gland at the base of the proboscis. The infected insect is now able by biting to communicate malaria of a specific type to man.

This is not the whole story. Some of the coccidia are found to contain not filaments but a number of dark, hard-shelled, cylindrical bodies ("black spores") of variable length and outline, which also upon rupture of the capsule are scattered through the anatomy of the mosquito, but have not been seen to enter the glandular cells. To these, in spite of numberless ingenious experiments and speculations, no satisfactory significance has as yet been assigned.

For a complete history of this brilliant scientific work (of which but the briefest outline is meant to be given here) readers of German are referred to the admirable account, with bibliography, given by Nuttall.[3] An interesting and useful sketch in English has also been made by Futcher.[4] In *Nature* for August 3, 1899, will be found a complete and elaborate technical description, by Ross, of the successive phases of the extracorporeal life of the parasite, together with an attempt at a more perfect classification and nomenclature of the *Hæmamœbidæ* than has thus far prevailed. It is announced that certain of the Italian

observers, Grassi, Bignami, and Bastianelli, have in preparation a series of plates, made from original sections and dissections, which will illustrate the cycle of changes observed in the mosquito in each of the several types of malarial infection.

The object of this paper is to describe some preliminary work of my own on the subject during the past August, September, and October, and to state briefly the problems that now lie before American workers in the same field.

There is a growing conviction among those best qualified to judge that among the mosquitoes (*Culicidæ*) the genus Anopheles will be found the only one that harbors the parasites of human malaria. Ross[3] dissected "quite a thousand" specimens (all the common species) of Culex inoculated with malarial blood, and failed in every case but one to find a single plasmodium. In the exceptional case he subsequently con-

cluded, with much reason, that he had found an avian parasite, the mosquito having perhaps previously bitten an infected bird. Koch[4] claims to have found near Grosseto in Tuscany one Culex pipiens with zygo-

tobiasts (*Sichelkeime*) in the poison gland. He offers no evidence to show that this was not also, like Ross's case, a Proteosoma infection.

Until definite proof to the contrary is forthcoming,

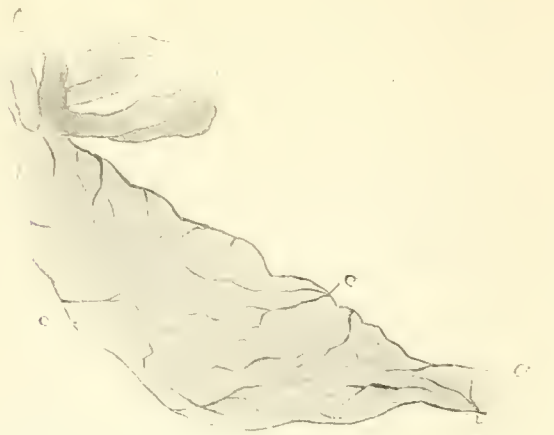

FIG. 3.—Stomach of normal Culex pungens (low power). *a*, Œsophagus; *b*, Malpighian tubules; *c*, *c*, minute air-tubes in the outer coating, just under the chitinous exoskeleton. Original dissection.

we may safely presume that Anopheles is at least the mosquito most often concerned in malarial propagation by suctorial insects.

The species of Anopheles in other parts of the world so far proved to be malaria-bearers are[1] A. claviger Fabr., A. pictus (or superpictus), A. nigripes, A. bifurcatus (probably a variety of nigripes), and A. pseudo-

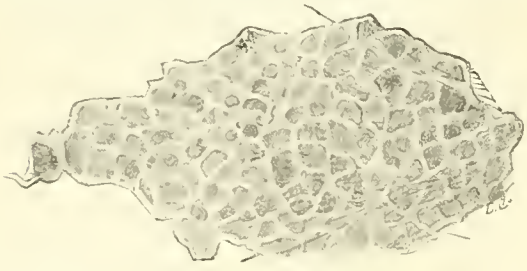

FIG. 4.—Epithelial layer and innermost muscular layer of stomach (Leitz objective 4), from near œsophagus; same dissection as Fig. 3.

pictus. Besides these are two or three species (not named—perhaps among the above) upon which Ross made his first experiments in India.

The first question of interest for American workers is, How many species of Anopheles are to be found in the eastern United States?

In Osten Sacken's "Catalogue of the Described N. A. Diptera" (second edition, 1878), the following list is to be found (omitting references):

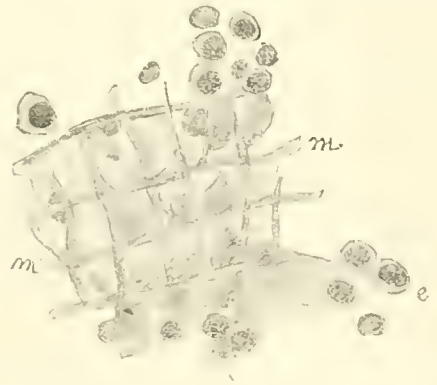

FIG. 5.—Transverse section of stomach of Culex. *e*, *e*, Gastric epithelium; *m*, *m*, meshwork of fibres in the muscular layer. ($\frac{1}{12}$ oil immersion objective, original preparation.)

1. A. annulimanus. Wisconsin.
2. A. crucians Wied. Maryland.
3. A. ferruginosus Wied. New Orleans and lower Mississippi.
4. A. maculipennis Meigen.
5. A. nigripes Staeger.
6. A. quadrimaculatus Say (A. pictus Loew). Atlantic States and Canada.
7. A. albimanus Wied. San Domingo.

It was not, I believe, the author's intention to make an exhaustive statement of the *habitat;* we may therefore view all of the first six as possible inhabitants of the eastern and southern United States.[1] Further study will doubtless indicate changes to be made in this list and additions to it. Mr. D. W. Coquillett, of the United States National Museum, kindly writes me (October 25, 1899) that he knows personally but three native species of Anopheles—A. crucians, A. quadrimaculatus, and A. punctipennis Say. "The last was set down by Osten Sacken as synonymous with crucians. It is undoubtedly a distinct species."

During late August, September, and October I have searched with some diligence in the neighborhood of

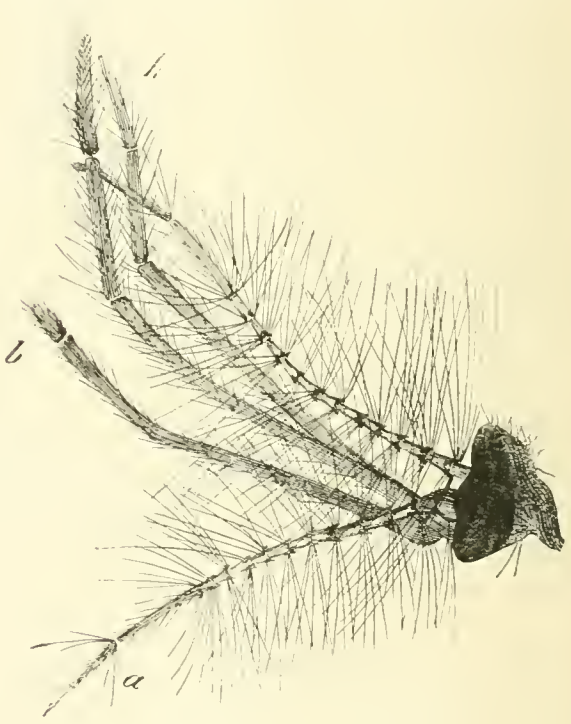

FIG. 6.—Head of male Culex (side view, head somewhat distorted). *a*, Antenna; *b*, proboscis; *h*, palpus. (Original preparation.)

New York for Anopheles, and have thus far not been able to find a single specimen. In Bronx Park, the open fields about Tremont, the vicinity of Port Richmond and West Brighton, Staten Island, and Corona, Long Island, there were hordes of Culex (several species), but nothing else. Acknowledging my own likelihood of error, the cold summer and early frosts were also perhaps responsible, since Anopheles appears considerably less resistant to low temperatures than Culex. At the last-named place, Corona, a part of which is admitted even by the inhabitants to be a plague-spot, I found a house on the edge of the swamps where there were three recent cases of malaria in one family. In one of the patients I demonstrated numerous tertian parasites in the peripheral blood. The other two were yellow and cachectic, gave a clear history of chills and fever on alternate days, and had improved on quinine. I made a thorough search of the walls and ceilings of the kitchen, basement, din-

ing-room, bed-rooms, and hall. No Anopheles was to be found—only Culex. In a florist's hot-house near

Fig. 7.—Head of female Culex (drawn by mistake from the lower instead of upper side). *e, e*, Compound eyes; *h*, palpus; *t*, proboscis; *a a* antennæ (only six of the fourteen joints drawn). (Original preparation.)

by I saw many and caught several specimens of Culex pungens, but no Anopheles.

My experiments have been, therefore, confined to Culex, and have been uniformly negative. A number of individuals from two or three different species were allowed to bite (tertian) malarial patients in the fever stage (103° to 105° F.) at Bellevue Hospital. Numerous intracellular and extracellular parasites were in each case found in the capillaries of the patient just before the inoculation was made. Of the stomachs thus far examined none differed essentially from the control preparation of normal culex-stomach figured here (Figs. 3 and 4). In Fig. 5 is drawn a 3 μ paraffin section of the stomach of a Culex killed on the fifth day after inoculation. In stained serial sections of the entire body (all carefully studied with the oil-immersion lens) I could find nothing in the least suspicious. I am still at work upon other specimens hardened for sections.

As regards the natural history of the *Culicidæ* a few notes, taken mainly from Wiedemann's and Meigen's large works, may be of use to students who have no access to a good entomological library. Belonging to the *Culicidæ* there are several genera (Aëdes and others — the classifications vary) besides Culex and Anopheles. Only the last two have thus far fallen under suspicion of conveying malaria. Culex has in the male (Fig. 6) upcurved palpi that are much longer than the proboscis; in the female (Fig 7) straight palpi much shorter. Anopheles (Greek ἀνωφελής, Latin *inutilis*, useless, harmful) has in the female (Fig. 8) palpi that are nearly or quite the length of the proboscis; and the proboscis itself is as long as the abdomen, longer and larger than in Culex. This difference can be noted in a moment with a hand lens. Another difference, readily noticed if the insect is caught sitting, is that Culex sits flat on the wall, while Anopheles sits with the body almost at a right angle. The larva of Culex breathes through a minute tube in the tail and swims perpendicularly in the water. The larva of Anopheles breathes by an abdominal trachea and swims flat. As to the species of both genera, identification requires no little practice, and the beginner had best send his specimens (properly mounted and labelled) to the Department of Agriculture in Washington, where I have found Mr. L. O. Howard and his associates most courteous and helpful. A. maculipennis Meigen (Fig. 9) is readily distinguished by the five spots on the wing (Fig. 10) and by two in-curved hooks near the anus. This is the species called A. claviger Fabr. by those European writers who follow the nomenclature of the well-known Danish entomologist Fabricius.[1] A. quadrimaculatus Say has two spots[2] on each wing. Wiedemann describes two large and two small spots. It is a large mosquito, biting fiercely in the spring, and is thought to hibernate in houses and cellars. A. punctipennis Say "has a large yellowish-white mark near the last fourth of the

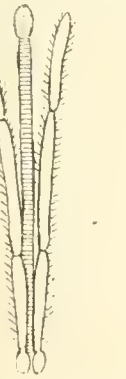

Fig. 8.—Proboscis and palpi of Anopheles maculipennis. (Enlarged from Meigen.)

Fig. 9.—Anopheles maculipennis, female (Enlarged from Meigen.)

costa" (Coquillett: personal letter). For minute details of these and the other species the specialists and special works must be consulted.

As to the malarial susceptibility of A. ferruginosus, crucians, punctipennis, and annulimanus, our native species, I know of no published observations. For physicians and entomologists in the Southern and Gulf States the study of these will be most fruitful.

In respect of the habits and mode of life of Culex I have nothing to add to the well-known facts save by way of confirmation. Culex is cleverly said by Ross to be a "pot-mosquito," Anopheles a "puddle-mosquito." This marks perfectly their habits of breeding. Culex lays its eggs by preference in pots, pans, barrels, wells, and other artificial accumulations of water. Anopheles lays in (or on hard substances near) pools in the fields or puddles in the streets and yards of marshy villages.[3] It is rarely or never in the stricter

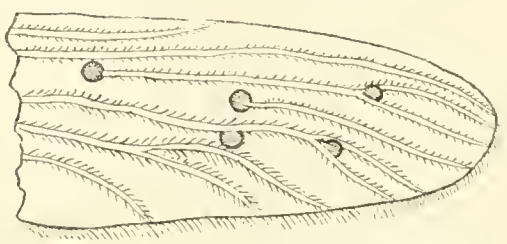

Fig. 10.—Part of wing of Anopheles maculipennis (From Meigen.)

sense urban. Both appear to prefer fresh water for breeding. L. O. Howard[4] says incidentally that water that is somewhat brackish will support mosquitoes.

[4] *Loc. cit.*, p 6.

Ficalbi (quoted in the circular of the British Museum, "How to Collect Mosquitoes") affirms that they will breed in salt pans and salt marshes, of even greater saltness than the sea.

In August Culex can be found in almost any New York back-yard where flowers and grass grow. I have found them in many yards in my own vicinity. Since the cold weather began (about November 1st) I found more than half a dozen females hanging dormant (the beginning of hibernation?) from bits of cobweb on the ceiling of my cellar. They readily revived and lived for days when carried to a warmer room. A few have been recently appearing every week or so in the well-warmed laboratory of the Presbyterian Hospital, where I could find no possible breeding-place except the closet-tank. Specimens healthy when caught, kept warm, and properly fed will live usually as long as one needs them, in large test-tubes or bottles stopped with cotton. A few blossoming stalks of fresh orchard grass appeared to make a good food. Some stayed well and active for seven to ten days (they were then killed) on nothing but a drop of fresh sugar-water every day. Dr. Bancroft (reported by Manson, *British Medical Journal*, April 2, 1899), of Brisbane, Australia, kept them alive in captivity for upward of six weeks on bits of fresh banana renewed every four or five days. Diluted honey is probably the ideal food. The larvæ will hatch readily in a warm place (75° to 80° F.) and well-kept females will often lay in captivity. Out of a dozen or so specimens of live Culex sent me by Dr. L. T. Royster, of Norfolk, Va., one or more laid eggs in a minute pool of water in the bottom of the test-tube on the journey. Unless starved for twenty-four hours the females will not always bite readily. In most species the males do not bite. I have usually applied Culex to the soft skin of the inside of the patient's arm, but when hungry they will even puncture the tough skin of the palm.

As to the limits of temperature favorable to the growth of the malarial parasite in the mosquito, it has been found by Grassi and others that about 30° C. (86° F.) is most satisfactory. Koch[1] believes that a night temperature in rooms of 24° to 25° C. (77° F.) will be found a minimum. Culex in my experience dies quickly in an incubator kept at 37° C., though my experiments were too few to exclude other possibly unfavorable circumstances.

There are numerous questions for which the investigation has so far found no answer. The rôle of the "black spores" is still a mystery. Whether or not mosquitoes directly infect one another or their larvæ, and whether the infected adult bequeathes the disease to the ovum, has not been determined.

A still more vital question is, Are there other modes of malarial infection than by the bite of suctorial insects? Ross, Manson, and Koch, whose wide acquaintance with similar biological processes elsewhere makes their opinion wellnigh a scientific induction, have unanimously answered in the negative.

The vast commercial and economic interests involved in the question whether malaria can be exterminated need be little more than mentioned. It seems likely that the problem will hinge on the destructibility of Anopheles. A large literature on the subject is already in print, to which there is no space here to allude. The plans comprise briefly: (1) drainage of the breeding-pools; (2) destruction of the larvæ and adults with chemicals, *e.g.*, kerosene and pyrethrum; (3) the cultivation of fishes in the pools, or of other insects like dragon-flies[2] that make mosquitoes their prey.

[1] *Loc. cit.*

[2] See an interesting paper by Beutenmuller in Lamborn's "Dragon Flies vs. Mosquitoes." New York: D. Appleton & Co., 1890.

One point of urgent and immediate practical value[1] is that the malarial patient should be isolated from mosquitoes and considered a source of danger both to family and community so long as he has germs in the peripheral blood.

121 East Twenty-sixth Street.

## THE SUBMAXILLARY PART OF THE OPERATION FOR EPITHELIOMA OF THE LIP.

By CHARLES N. DOWD, M.D.,

New York,

Attending Surgeon to the General Memorial Hospital.

In March of last year the writer published, in the Medical Record, a plea for the exploration of the submaxillary spaces in patients from whom small epitheliomata of the lip were removed, and cited instances in which infected lymph nodes were found there, even when the epitheliomata of the lip were very small. Further developments in some of the cases referred to and facts observed in other cases make it desirable to bring the subject again before the medical profession, particularly as there have appeared within the current

Fig. 1.—Incision for the Submaxillary Part of the Operation for Epithelioma of the Lip.

year at least two articles, one in a leading American and one in a leading German journal, advocating plastic operations on the lip for cancer, but not suggesting the removal of lymph nodes beneath the jaw. One wonders why the contiguous lymph nodes are not more generally removed for cancer of the lip, when they are almost universally removed in operating for cancer elsewhere. Hardly any surgeon would remove a cancer of the breast without removing the axillary lymph nodes, yet it is still common to remove a lip cancer and not touch the submental and submaxillary nodes.

[1] Koch: *Loc. cit.*

Two possible explanations suggest themselves: 1. Many cases are known to have been cured by the simple excision of the growth from the lip. 2. Physicians generally believe that they can feel the submaxillary or submental nodes if they are infected.

Fig. 2. — Exposure of the Mylo-Hyoid Muscle, after the Skin, Superficial Fascia, Platysma, and Deep Fascia have been divided and retracted.

In answer to the first statement, it may be said that although many patients do recover from whom the lymph nodes are not removed, many others die because they are not removed. Fricke[1] has recently reviewed the histories of one hundred and fourteen cases of cancer of the lower lip treated in the Göttingen clinic from 1874 to 1896, and calls particular attention to the frequency of lymphatic involvement even when the primary growth is small. As there were only three cases of local recurrence in the entire number, the cure of the local growth can almost certainly be accomplished by excising it at a distance of one centimetre from its visible or palpable border; but the great majority of the deaths came from metastasis which resulted from lymphatic infection. The cancerous condition of the lymph nodes often existed when the lip ulcer was no larger than a hazel-nut; in one instance it was present in the submental nodes when the lip sore had been present only six weeks, and was small and not ulcerated, and the nodes could not be distinctly felt before operation. His statistics, which are in the main similar to those of other observers, indicate recurrences, or metastasis, in thirty-two per cent. of the cases, three-fourths of which were in the neck or under the jaw or in the jaw.

Gussenbauer,[2] as previously stated, found evidences of malignant infection of the lymph nodes in twenty-nine out of thirty-two ordinary cases of lip cancer. It is manifestly wise to turn our attention to the lymph nodes in all cases of lip cancer, even though some patients will recover without it.

As to the belief that the lymph nodes can be palpated if they are diseased, it is true that they can be in the great majority of cases; but the examination is so often made without counterpressure within the mouth in just the right places, that enlarged nodes frequently escape detection. Within the current year I have seen several experienced physicians and surgeons examine a patient with a small lip cancer, and fail to discover enlarged submaxillary lymph nodes, and yet at the operation several were removed as large as filberts. Again in some instances they are without doubt infected when they cannot be palpated before operation. It is far safer to make exploratory incisions in all cases than to rely on palpation to discover enlarged nodes.

In the previous paper exploratory incisions were advocated which were located beneath the margin of the jaw, and which extended forward about one inch from the facial artery, the incisions being extended in either direction as was necessary to remove all infected lymph nodes. Two patients operated upon by this method have since shown recurrences, one of them, sixteen months after operation, in the submental group, and nine months after that in nodes situated just beneath the margin of the jaw at the posterior margin of the submaxillary salivary gland, and seven months later in the nodes beside the internal jugular vein. The other patient had a recurrence fifteen months after operation in nodes at the posterior margin of the submaxillary salivary gland. It is not certain that these nodes would have been found at the time of the first operations if longer incisions had been made. They could not be palpated, but their involvement indicates the desirability of carefully inspecting the locations in which they lie.

At least three localities should be examined in order to make a proper exploration of the lymph nodes beneath the jaw, which are likely to be infected in lip cancer.

Fig. 3.—Exposure of the Submaxillary Salivary Gland after the Mylo-Hyoid has been drawn forward. The gland is drawn downward so as to show lymph nodes above its anterior border which are nearly constant, and lymph nodes at its posterior margin which are sometimes found.

[1] Theodor Fricke: "Beiträge zur Statistik des Lippenkrebses." Deutsche Zeitschrift für Chirurgie, Band 50, Heft 1.

[2] Gussenbauer: Zeitschrift für Heilkunde, 1881, Bd. ii., S. 17

I. The region above the anterior part of the submaxillary salivary gland. There are regularly two or three nodes here, and they are the ones most commonly affected.

II. The space under the chin between the anterior bellies of the two digastric muscles; there are regularly two or three nodes here, and these are the ones next most commonly affected. They are sometimes called the submental nodes.

III. The region beneath the border of the jaw about the posterior part of the submaxillary salivary glands; the nodes here are less commonly affected.

In addition to these three localities, the region of the internal jugular vein should be explored when the submaxillary nodes are decidedly infected. Incisions two and one-fourth to two and one-half inches long should be made. They should be beneath the margin of the jaw as shown in Fig. 1. Scars in this region which are parallel with the jaw border show hardly any tendency toward stretching.

After cutting through the skin, the superficial fascia, the platysma myoides, and the deep fascia, the mylohyoid muscle is brought into view. If this is pulled well forward, and if the two margins of the wound are also strongly retracted, the submaxillary salivary gland comes well into view. It may be loosened or drawn down so as to expose well its upper anterior surface, and the nodes which regularly lie above it there may be removed. If they appear infected and adherent to the salivary gland, that may also be removed, but it is seldom infected. The retractors should then be applied to the posterior part of the wound, and the tissues under the margin of the jaw should be inspected as far back as the parotid gland. Frequently two or three nodes are found just back of the submaxillary salivary gland, which should be removed.

After this is accomplished the retractors should be put in the anterior part of the wound, and the dissection carried forward to the submental nodes. There are usually three of them, and they lie about one-half to three-quarters of an inch below the symphysis menti, between the anterior bellies of the two digastric muscles.

If the nodes beneath the jaw are found infected the deep chain of lymphatics which accompanies the internal jugular vein should be examined. The upper part of this chain can be reached through the incision already made, but if it is necessary to remove nodes from the lower part of the chain an incision along the course of the carotid is desirable.

In closing the wounds careful apposition of the skin edges is important, and the subcuticular stitch is best adapted for the purpose. A small opening in the middle of the incision may be left through which a bit of rubber tissue may be put for drainage, since the proximity of the mouth and ether cone makes it difficult to preserve asepsis. This is to be removed in forty-eight hours if healing is progressing satisfactorily.

The ultimate results of this operation cannot yet be determined, but as some method of removing the lymph nodes from beneath the jaw in cases of lip cancer is coming more and more into general use, we may expect reports in due time. The particular purposes of this communication are to call attention again to the desirability of removing the nodes from beneath the jaw, and to indicate the exact location of the nodes most likely to be infected, and the way of reaching them.

---

Soaps containing antiseptics have been found to possess less antiseptic power than the same amount of such substances without the soap. In disinfecting the hands, a non-antiseptic soap can first be used, and the desired antiseptic afterward applied to greater advantage.

## THE PREVENTION OF CONTAGIOUS DISEASES.[1]

By FRANK W. WRIGHT M.D.,

HEALTH OFFICER, NEW HAVEN, CONN.

It seems to be the custom for sanitarians to discuss fanciful theories rather than the practical questions that are daily met by those actively engaged in municipal sanitation. Contagious diseases we always have with us, and their suppression, or at least minimization, is of vital importance to any community.

It is expected that he whose duty it is to assist in preserving the health of a community will be progressive, and attempt by all means that are practicable so to educate the people as to the measures necessary to accomplish this, that they will co-operate; but when his views are so far advanced, both in theory and practice, that they cannot be understood, or he attempts to enforce the law so rigorously that the people consider their rights to be encroached upon, he is going beyond his duty, and doing irreparable injury to the cause. That there is a gradual advance in public sentiment is certain, and it is just as certain to those whose duties bring them almost constantly in contact with contagious diseases that measures cannot be successfully enforced that do not have the support of public opinion, and that this opinion will sustain more and more rigid measures as fast as it is demonstrated that good comes from them.

From a very early period in the world's history, it has been recognized that certain diseases were in some way conveyed from place to place and from one person to another, and there has been some attempt to limit these diseases when they became epidemic. That these diseases were rendered more communicable by certain acts of mankind, was also recognized. As early as 1500 B.C. the Egyptians formulated certain hygienic rules. The ancient Jews also enforced many sanitary regulations, but to give them the strength and support of public sentiment they were made religious rites. As the world became more enlightened and these diseases have become better understood, more effective regulations have been adopted. It is to be presumed that in all these years there have been many persons, as there are at the present time, who could not see the wisdom of these regulations, and consequently put many hindrances in the way of those who were to enforce them. At certain periods the cause of contagious and infectious diseases was attributed to conditions of the earth and atmosphere, and it is not improbable that, to a certain extent, such is the case, but these conditions must be regarded as secondary to the now generally accepted causes. It is only within very recent years that anything definite has been known as to the real cause of a contagion being conveyed from one person to another. Bacteriologists have shown us that the causes are micro-organisms that are capable of being conveyed from place to place and from person to person, and that contagious and infectious diseases only invade new localities as communication by persons and commerce acts as their means of locomotion. Bacteriologists, in studying the life of these germs, have also studied how they may be destroyed. They have gone still further, and in a few instances have produced an antitoxin, and as time goes on will produce more, so that it is very probable that many living to-day will see antitoxins for both the curative and preventive treatment of nearly all of the diseases caused by micro-organisms.

To cause a contagious disease there must be at least two conditions: first, there must be the poison or germ of a particular disease, and next there must be a peculiar susceptibility, whatever that may be, to this dis-

[1] Read before the American Public Health Association, November 1, 1899.

ease. Neither one of these conditions in themselves can do harm, but by bringing them together the disease results, which in turn produces more micro-organisms, and these being disseminated may meet other susceptible persons.

To prevent the spread of these diseases, two objects must be accomplished: first, the destruction of the poison given off from the sick one, which is called disinfection, and second, the prevention of any poison that has escaped disinfection from coming in contact with susceptible persons; therefore isolation. There is one other way in which certain diseases may be limited—that is, by rendering persons immune by inoculation, as in smallpox and diphtheria, it being now practically impossible for the former of these diseases to obtain a firm foothold in any well-vaccinated community.

If, therefore, isolation and disinfection, which are so easy, will prevent contagious diseases, why are not these complaints entirely done away with, or at least reduced to a minimum and kept there?

The answer to this is the practical side of the question. Theoretically isolation and disinfection are possible, practically they are not; and why? Because of the lack of co-operation by all and the indifference of many. The persons who can, and do, do the most to assist in this labor are the members of the medical profession. These, by the nature of their close relation with the family, are in a position to advise as to the measures to be pursued in a home attacked by a contagious disease; they can report their cases promptly to the authorities, that others may be warned and official action may be taken to confine the disease; and they may also render substantial aid by expressing confidence in the authorities and in the regulations. This by far the larger part of the profession do. But there are enough physicians in every community, who are inspired either by petty jealousies or pure perverseness, who conceal their cases, or report them too late for the public to be warned; who neglect to instruct the family as to precautionary measures; who cast insinuations upon the competency of the officials of the health department, and evade as far as possible all regulations. Some even go so far as to advise those who place implicit confidence in them, that the whole business amounts to nothing. The presence of half a dozen physicians of this kind in a community interferes with any system and renders ineffective the services of a hundred who lend their support.

The people themselves are gradually becoming aware of the fact that contagious diseases can be controlled by attention to disinfection, and that the sick should be separated from the rest of the family. It is truly surprising to see the zeal certain persons exhibit when their neighbors are afflicted, but they themselves illustrate that "familiarity breeds contempt," when their own families are attacked, and disregard all sanitary precautions. This feature is not confined to the ignorant, but rather is to be seen among those who are regarded ordinarily as intelligent people.

One may pertinently ask, Why not enforce the laws? My experience is similar to that of others, namely, that the courts do not sympathize with the health department, and will not prosecute those who flagrantly violate the health ordinances; or, if they do, they either require impossible evidence, or push the matter with so little energy that the effort reacts to the injury of the department.

The effectiveness of the sanitary work of a city is in direct proportion to the amount of money allowed for it by the city councils. The suppression and care of contagious diseases are necessarily expensive, but as politics in a considerable degree control appropriations it cannot be expected that non-partisan health boards will be generously dealt with. As it now is, an injustice is done to the poor man whose family is attacked, if the case is reported. His boss, who, when he has the same trouble in his own family, insists there is no danger, immediately lays him off from work. He thus loses his source of income, and is obliged to run in debt or become a public charge. Consequently he conceals, if possible, any sickness of a contagious nature in his household.

There are certain persons who argue that our most common contagious diseases are maladies that can best be borne during childhood, and that by preventing them during that period, or in early youth, we are rearing a population of adults who are liable to contract these complaints with more fatal and disastrous results both to the afflicted and to the community in which they reside. These people, by their actions and influence, greatly obstruct the work of health boards.

Epidemics do not often arise as such, but have their origin usually from a small beginning, gradually spreading from person to person, costing valuable lives and much money, which might have been easily avoided by a little care at first and a few well-spent dollars. The first requisite is uniformity in health laws and usages, thoroughness in any locality being to an extent useless, if an adjoining town is negligent in adopting and enforcing proper precautions. A medical man should inspect the schools daily, and examine each child that seems to be ailing; he also should inquire into the cause of illness of those who are reported sick, and in case of doubt personally examine them. If a disease at all suspicious should be found, all children of the family should be excluded from school until an accurate diagnosis can be made. The writer is convinced that children with mild cases of diphtheria and scarlet fever occasionally attend school throughout the whole course of the disease.

A good hospital for the exclusive accommodation of those suffering from contagious diseases should be maintained in every city. The writer found a short time ago, by inquiry, that of the sixty-two principal cities in the United States and Canada, less than one-quarter were provided with decent hospitals for contagious diseases, some not even having a place for the care of smallpox. All cities should be compelled by law to provide a hospital for the care of these diseases. Smaller places could easily and cheaply provide sectional hospitals, that could be taken down and transported from place to place as required for the use of those who could not receive proper domiciliary care. Such buildings would possess the advantage of being easily disinfected. A hospital to be complete would necessarily require modern disinfecting apparatus, an ambulance, trained service, and a detention building for the accommodation of those suspected of having a contagious disease. In addition, boards of health must have liberal appropriations of money for the care of the sick, and the full and free support of the medical profession and of the public at large. The dread of smallpox at this time is so great that public sentiment will sustain any measures for its suppression, no matter how radical. This same feeling is gradually being developed in regard to scarlet fever and diphtheria, but it has not reached the point where it demands the prompt and decisive action which it should. It does not always sustain such action, which is just as essential as the work itself. The expense of limiting these diseases would at first be great, but if we could with accuracy determine the aggregate expense to both individuals and municipalities, I am convinced it would be found that it is costing more now than would be necessary to carry out a good system. The writer makes the following conservative estimate of the average cost of a contagious disease under the present system.

One person at least is thrown out of employment on

account of every contagious disease; often several are obliged to remain from their work. Basing the estimate upon the assumption that this person can at least earn a common laborer's pay—$1.50 a day—and that he will be compelled to lose this for two weeks or twelve working days, we find that he loses $18 from his earnings. Happy is he who escapes with a bill for a like sum for medical attendance; $36 for lost time and the doctor. Now with medicine, nursing, and articles destroyed the sum is easily increased to $50.

This altogether too conservative estimate places on the average the direct cost to the head of the family in which the sickness occurs at $50 if the patient recovers. Indirectly the cost may be vastly more than this.

The comparison of the origin and spread of these diseases to a fire is old, but appropriate.

It will be practically impossible to prevent isolated cases now and then occurring until bacteriologists have taught us more concerning the micro-organisms that cause them, and every city and town has adopted the same stringent regulations and makes sure they are carried out in detail. Then, when from an isolated case the disease spreads and other cases occur, some one will be responsible, as all great epidemics, like great conflagrations, usually begin with such small proportions that almost any well-directed effort to subdue them at an early stage would be successful. Health departments should be as well or better equipped than fire departments; as when a flame is quenched, no matter how great the threatened peril at first, the danger is gone; with the alarms the health department receives, the danger only begins, the flame burns constantly for weeks and is liable to break out with renewed vigor at any moment, until the patient has recovered and every article which may have been in the least infected has been disinfected. Thus for a long time does one single case of a contagious disease require constant vigilance. All cities maintain at great expense well-equipped fire departments. Why not have the health department as well equipped, so that when a physician is called to see a sick person and makes a diagnosis of a contagious disease he may immediately notify the health authorities, who have a representative constantly ready to respond at once to the call? This person without delay visits the place, and if he is convinced that the patient can be isolated at home so as to expose none but the necessary attendants, he should be allowed to remain there, but the portion of the house not used for the sick person's care should at once be disinfected. The responsibility of the health authorities should not end until the patient has recovered and everything has been disinfected. Until then they should have personal knowledge that their rules and regulations are being fully complied with. If, on the other hand, as in the majority of cases is likely to happen, it is found that the sick one cannot be completely isolated, or that from any cause others may be endangered, the ambulance should be at once summoned and the patient removed to the hospital, and at the same time all articles which have been subjected to infection and can be transported should be taken to the disinfecting plant and sterilized. These can be returned within twenty-four hours, or as soon as the house is ready to receive them. When the sick person and infected articles have been removed, a corps of trained and reliable assistants should immediately cleanse with disinfecting solutions any room or portion of the house which could possibly in the future be a source of danger. As soon as all this is accomplished the bread-winners of the family could pursue their usual vocations.

This plan, when put to the test, may need modifications, but in the main could be carried out. The expense, which upon first thought would seem to be very great, would not be so large as to render it impracticable; as, after the plant was once established, the number of persons constantly employed would be small. In times of need, outside help could be secured.

Undoubtedly, many lives are sacrificed by contagious diseases yearly that could be saved if all persons would conscientiously give attention to details and lend their support both morally and financially.

## LIGATURE OF THE FIRST PORTION OF THE LEFT SUBCLAVIAN ARTERY FOR ANEURISM; DEATH AFTER FOUR WEEKS.

By F. KAMMERER, M.D.,
NEW YORK.

In view of the fact that ligature of the left subclavian artery within the thorax has perhaps never before been attempted, I venture to report the following case:

L. W——, aged forty-seven years, was admitted to the German Hospital, in New York, on September 27, 1899. Twenty years ago he had contracted syphilis, but had had no secondary or tertiary lesions, according to his statement. In July of this year, he for the first time noticed a small swelling in the left supraclavicular region. He distinctly stated that he had received a blow at this point, some weeks previous. The growth gradually increased in size until he came to the hospital. For three weeks he had noticed a numbness in the third and fourth fingers of the left hand. When I first saw him, a tumor, about as large as a man's fist, was present in the region above stated. The tumor was in part covered by the sternal end of both the left sterno-mastoid muscle and the clavicle. It entirely filled the angle formed by them, and overlapped the clavicle to a slight extent. Immediately above the clavicle, it was in close relation and adherent to the skin covering it. The pulse at the radial artery was scarcely retarded on the left side. Expansile pulsation of the tumor was very marked. There was no dulness on percussion of the anterior upper part of the thorax.

The case seemed a very urgent one indeed, more especially as the aneurism was already adherent to the skin above the clavicle and evidently preparing to rupture. I therefore concluded that palliative treatment would be of little value, and that the patient's only chance lay in ligature of the subclavian on the cardiac side, the distal ligature being unavailable owing to the many collateral branches of the sac. I was encouraged in this view by the belief that the aneurism did not extend for a great distance into the thorax, and, secondly, by a perusal of Wyeth's able article on "Special Aneurisms," in his "Text-Book of Surgery," where the author gives a more favorable prognosis of ligature of the left than of the right subclavian artery. He bases this opinion mainly on the unfortunate position of the innominate artery, which is in a direct line with the impact of the blood current forced out by the left ventricle. The operation was performed in the following manner, on October 18, 1899:

Under chloroform a transverse incision passing over the ends of both clavicles and the manubrium of the sternum, fully six inches in length, was made. A vertical incision in the median line of the body, beginning at the cricoid cartilage and meeting the transverse incision on the sternum, was now added. The flaps thus outlined were dissected from the underlying parts. With the help of Gigli's saw, about one and a half inches of the right and two inches of the left clavicle, bordering on the sternum, were resected. The aneurism was in such close relation to the left

clavicle that great care had to be taken at this stage of the operation. The upper end of the sternum was now removed for about a half an inch. The two innominate veins were thus exposed, whereupon it became apparent that access could not be had to the left subclavian artery, owing to adhesions of the left subclavian vein with the aneurism, as a result of which the space between the first left rib and the left innominate vein was entirely too small for any manipulations at such depth as is made necessary by the course of the subclavian artery after its origin from the aortic arch. I, therefore, resected two inches of the sternal end of the first rib, and removed the corresponding part of the manubrium. Even now, the arch formed by the superior cava and mainly by the left innominate vein, below which, of course, I had to search for the subclavian artery, proved a great hindrance, as I did not venture to dissect the innominate vein from the aneurismal sac. Two blunt curved retractors were inserted below the venous arch, and the latter was, with great care, pulled somewhat in an upward direction, out of harm's way. However, during the entire operation, I was in continual fear of a lesion to these vessels, as at times strong traction had to be exerted upon them. I now separated the tissues to the left of the three arteries springing from the arch of the aorta, with my fingers, and as I was doing this I could very distinctly, in turn, recognize by the touch first the innominate, then the left carotid, and finally the left subclavian artery, the latter at about a distance of two and a half inches from the posterior surface of the sternum. When pressure was exerted upon the subclavian with the tip of my finger, forcing it toward the vertebral column, pulsation immediately ceased in the aneurism and in the left radial artery. Under such circumstances, it was impossible to expose the subclavian artery to view, and then to separate it from its sheath. To accomplish the latter, I had to rely upon the sense of touch, and separation of the artery from the surrounding tissues was done entirely by the aid of my left index and a pair of long curved scissors, which were not used as a cutting instrument. Contrary to my expectations, I succeeded in this very well, and I soon had the vessel sufficiently isolated to think of passing a ligature around it. This proved a very difficult task, however, and it was only after many and prolonged attempts that I succeeded in passing an aneurism needle and a thread. With the assistance of the latter, I also passed the ligature beneath the artery. It consisted of several pieces of strong chromicized catgut, wound together. I now tightened the first hitch of a surgical knot until I felt a resistance, and until pulsation in the aneurism and the arteries of the left upper extremity entirely ceased, my object being to stop the circulation, but not to injure the coats of the vessel. The knot was now completed. No drainage was established from the seat of the ligature, but the soft parts were allowed to come together, closing the deep wound cavity. The vertical incision was entirely closed by sutures, as were also the ends of the horizontal incision, thus covering what remained of the clavicles. The remainder of the wound was covered with loose gauze. The operation had lasted over three hours.

The course of the case for the first three weeks was entirely uneventful. After the first few days, the patient's temperature and pulse became practically normal, and the wound cavity was soon lined with healthy granulations and filled up rapidly. On the day after operation, there was no pulse in the left radial nor in the aneurism. The latter had decreased considerably in size. The left arm was not swollen, nor was its temperature appreciably lowered, and sensation and muscular power were intact. On the following day, October 20th, there was faint pulsation at the left radial, but none could be detected in the aneurism, and sensation in the arm was slightly retarded.

October 22d: Sensation was apparently normal in the left arm.

October 23d. The pulse at the left wrist was somewhat stronger.

October 25th: The patient complained of shooting pains in the left arm.

October 30th: There was slight œdema of the left hand.

November 3d: The œdema of the left upper extremity had increased a little. The patient continually complained of intermittent shooting pains in the left arm. The pulse in the left radial artery was no stronger than on the third day after operation. There was not the slightest pulsation in the aneurism; the sac was firm and not compressible.

November 6th: On that day the patient complained of a feeling of weakness. Temperature, 101° F.; pulse, 120. On removing the dressings, it was seen that they were saturated with a considerable quantity of fresh blood. Several clots were found on the wound surfaces, which otherwise had the appearance of healthy granulations. On the left side, near the aneurismal sac, a blood clot lay, which was firmly attached to the surrounding tissues.

From this time until November 15th, the dressings, which were changed at least once a day, were always filled with blood, although when they were removed no bleeding point could be found on the granulating surface; the temperature had risen to 103° F. nearly every day since the hemorrhages began, and the pulse ranged between 110 and 130.

November 15th: The patient showed the effect of the continuous loss of blood during the last ten days. At 1 P.M. there was a sudden and very severe hemorrhage, saturating the dressings and the bed linen. Pulse, 140 and very weak. There was slight collapse, but he rallied well.

November 16th: At 4 A.M. another hemorrhage occurred. Pulse, 154, hardly perceptible. At 2:15 P.M., death from exhaustion took place, on the thirtieth day after operation.

At the autopsy, it was found that the hemorrhages had been caused by rupture of the artery at the site of the ligature. The wound was in an aseptic condition. The loop of chromicized catgut had been to a great extent absorbed, especially at the point immediately opposite the knot, but a few strands were still present here, to hold the loop together. The latter had cut through the coats of the artery and almost completely severed the vessel; but it was still lying within the lumen. The knot, however, rested on the outside of the vessel. The distance from the aorta to the ligature was one inch. There was not the slightest trace of a clot on the proximal side of the ligature. The aneurismal sac was lined on its inner surface with a layer of fibrin, varying from one-half an inch to an inch in thickness.

The left subclavian artery has to my knowledge been tied twice before in its first portion as it emerges from the thorax, once by Kearney Rodgers in 1845 with a fatal result, and once by Halsted during extirpation of an aneurism as a preliminary step. His patient recovered. In my own case the situation of the aneurism made such a procedure impossible and necessitated the application of a ligature nearer the aortic arch. The unfortunate final result after an undisturbed course for several weeks was rather discouraging. I had used an absorbable ligature, and the wound surfaces had closed around the same without suppuration—two requisites for a favorable result after deligation of large arteries. Whether or not I avoided rupturing the inner coats of the artery while tightening the first hitch of the surgical knot, I cannot

say—a very important point, according to the experiments of Ballance and Edmunds, Senn, and others. "The living and uninjured wall is the only true safeguard against hemorrhage," to quote Ballance and Edmunds, and this must be especially true of the first portion of the subclavian in man, as the walls of this vessel are exceptionally thin in proportion to its size. The clot on either side of the ligature has really little to do with the tissue transformation that occurs within the uninjured vessel and about the aseptic ligature, leading to permanent occlusion of the artery. Some authors (Bruns) even believe that when the coats are not ruptured clotting does not occur. In my case there was no trace of a clot on the proximal side of the ligature, but I cannot accept this as a proof of my not having injured the coats during application of the ligature. Senn's plan of applying two ligatures, at some distance from each other, thus leaving a bloodless space between them, was not applicable to my case. Nor did I feel that I could have applied a stay-knot, as Ballance and Edmunds recommend, with any amount of exactness, owing to the depth of the wound. Still it seems to me now that an attempt should always be made, in ligating large arteries, to pass several ligatures. We will thus most readily avoid injury to the coats of large vessels and succeed in arresting the circulation.

## Progress of Medical Science.

**Giant Cells in Carcinoma.**—In an examination of four tumors of carcinomatous type obtained from operations J. A. Becher (*Virchow's Archiv*, 156, p. 62) advances a theory of the production of the giant cells which are so frequently found about the "epithelial pearls" in these tumors. The tumors were of the following types: (1) Carcinoma of the foot, developed from an unhealed injury of the soft parts, (2) carcinoma arising in a fistulous tract in a femur which was the seat of osteomyelitis; (3) carcinoma of the lower lip; (4) carcinoma formed at the base of a degenerated lipoma of the back. The giant cells surrounding the "pearls" and, in case 4, also about the hyaline connective tissue, are to be looked on as foreign to the tumor cells proper and possessed of amœboid and phagocytic properties. They form themselves in the periphery of the tumor about the "pearls," surrounding them, breaking in between them, and finally destroying them; while the process ends with complete organization of the carcinomatous nodules with young connective tissue. Thus the process may be looked upon as one of constructive repair and a type of healing. The appearance of the giant cells is not only facilitated but stimulated by long-continued inflammatory processes incidental to the slowly developing tumors. Becher maintains that the giant cells are developed from the connective-tissue cell, though in one case the evidence seemed to point to the epithelial cells as giving origin to the phagocytes. The positions assumed by the giant cells are similar to those found in tubercle tissue, in which, as is well known, the phagocytic function is maintained, though Langhans assumes that the peripheral position in the tubercle is a secondary process brought about by toxic, trophic, or mechanical changes. With reference to the genesis of the cells, Becher maintains the position adopted by Marchand, that they are in reality types of myelocytes. The young mononuclear cell undergoes the mitotic process, but no actual division of the protoplasm takes place. The nucleus, however, divides, and thus the multi-nucleated cell arises, which cell by means of its increased proportion of nuclear substances possesses much greater energy than an ordinary cell, and can thus act better as a destroyer of poisonous agents. Thus in an indirect way this point of view would uphold the parasitic nature of the carcinomatous process. The ultimate destiny of the giant cells is not yet thoroughly determined, but the greater number of them undergo fatty degeneration.

**Pathology of Ovarian Dermoid Cysts.**—The latest researches have shown a distinct difference between dermoid cysts of the ovary and those of other regions of the body. The contents of the former, though for the most part composed of cells arising from the epiblast, also contain tissues derived from the other embryonic layers of the body. An interesting case in point is described by Arnsperger, of Heidelberg (*Virchow's Archiv*, 156, p. 1, 1899), of a young woman aged twenty-seven years, in whom there was found a typical ovarian cyst. In the wall of this cyst, bulging inwardly, were two rounded masses, the smaller one of walnut size, which merged into one another. Both were covered with a hairy skin, and both histologically and anatomically the masses might be said to have been rudimentary embryos. Thus there were present a central nervous system in the smaller one, epidermis, skeletal frame, and a tube-like structure resembling the trachea, attached to which was a well-formed alimentary canal. This latter may be said to be a rare find, for usually the ectoderm tissues predominate. After mentioning other noteworthy recorded cases of like kind, the author dwells on the origin of the dermoid ovarian cysts. In this connection he brings out the resemblances existing between these tumors and the Graafian follicle. He agrees with Wilms and others that the fully developed ovum is the mother soil of these cysts. Further than this, it can be said only that a process of accretion of the ovum leads finally to the formation of dermoids and teratomata. Whether, at the very beginning, the cyst arises from an undeveloped double ovum or from the union of ova of different Graafian follicles is still a matter of hypothesis. Richter's theory, of the union of two ova, one fertilizing the other, a sort of parthenogenesis, is that adopted by the author. Dermoid cysts of the scrotum resemble completely those of the ovary, and, it may be inferred, are developed in much the same way from an original sex cell. They are almost always congenital. If not, however, it might still be possible to trace their origin to an ovum which remained undeveloped until later life.

**Vaginal Hysterectomy for Carcinoma of the Uterus.**—Jessett (*Lancet*, November 18, 1899, p. 1359) reports the results of vaginal hysterectomy for carcinoma of the uterus in one hundred and seven cases operated on during seven years. Nine of the patients died from the operation—3 from shock, 2 from intestinal obstruction, and 4 from peritonitis. Of the whole number 4 were operated upon in 1892, 17 in 1893, 22 in 1894, 16 in 1895, 18 in 1896, 18 in 1897, and 12 in 1898. Of the 4 patients operated on in 1892, 1 is known to be well; 1 died within a year from recurrence; 1 had an early recurrence; and 1 was lost sight of. Of the 17 patients operated on in 1893, 1 died from septic peritonitis, and 6 had recurrence and died within a year. Of these 1 died within three months from a secondary growth at the pylorus, and 1 nine months after the operation from a secondary growth in the intestine. There was no local recurrence in either case. Three of the patients were lost sight of, but they were well twelve months after the operation, and the remaining 5 were free from recurrence two and three years after the operation. Of the 22 patients operated on in 1894 early recurrence took place in 5, and 3 died from the operation—1 from shock, 1 from intestinal obstruction, and 1 from peritonitis. One patient

died twelve months after the operation from other causes, and there was no local recurrence. Seven patients were well from nine to fifteen months after the operation, and the remaining 6 were well two years afterward, and so far as is known without recurrence. Of the 16 patients operated on in 1895 early recurrence took place in 5, in 2 within a year, in 2 within two years, and in 1 within two and a half years. The remainder were well when last seen, 4 of these quite recently. Of the 18 patients operated on in 1896, 2 died from septic peritonitis, recurrence took place in 5 within a year, and 1 died within a year from secondary glandular involvement, but without local recurrence; 2 patients were lost sight of, and the remainder were free from recurrence when last heard of. Of the 18 patients operated on in 1897, 2 died, 1 from intestinal obstruction and 1 from peritonitis. In 3 early recurrence took place, in 1 secondary deposits in the abdomen, 2 were lost sight of, and the remainder were free from recurrence when last seen. Of the 12 patients operated upon in 1898, 1 died. This was a case of combined abdominal and vaginal hysterectomy, the carcinomatous uterus being also the seat of several myomata. In 1 case immediate recurrence took place; of the remainder it is yet too early to make any comment, although they are free from recurrence. Two of the cases were complicated by the presence of ovarian cysts, which were tapped through the vagina, and their contents removed. Both patients recovered. In 5 cases myomata were present, in 4 instances necessitating the performance of the combined abdominal and vaginal operation. Two of these died from shock. Myomata of smaller size were present in several other cases, and in these the diseased organ could be removed through the vagina. In 13 cases the seat of the disease was limited to the body of the uterus; in the remainder the disease commenced in the cervical canal or the enlarged os, and in many of these the mucous membrane of the vagina was more or less invaded.

**Obstruction of the Pylorus by New Growths.**—Allaben (*Journal of the American Medical Association*, November 25, 1899, p. 1338) records a case of obstruction of the pylorus due to the presence of a new growth in which pylorectomy was performed, with a successful result. As an outcome of his study of the subject he submits the following conclusions: Carcinoma is one of the most potent factors in the causation of death, with a tendency to increase constantly in frequency of occurrence. The stomach is involved in about one-fifth of all of the cases of primary carcinoma, the pyloric region being affected in sixty per cent. of the stomach cases. The treatment of gastric carcinoma having in view a permanent cure is in the present state of knowledge limited wholly to surgical methods. As early total extirpation of malignant growths with the hope of permanent cure is the goal to be reached, and as these growths occur with such frequency at the pylorus, it would seem to follow as a natural conclusion that pylorectomy would be the treatment most frequently employed for the cure of this malady. Inasmuch as early diagnosis is the most important requisite for the institution of proper radical treatment, the clinician and the surgeon should concentrate their best efforts in this direction. If the operation of pylorectomy be performed before symptoms of obstruction manifest themselves, and before the occurrence of metastasis, the immediate result will be as favorable as is obtained in any other form of abdominal surgery, and the remote results as good as from extirpation of carcinoma of the breast.

**Successful Removal of a Bullet Lodged in the Brain for Nine Months.**—Bampton (*British Medical Journal*, October 28, 1899, p. 1189) reports the case of a lad who shot his brother accidentally with a pistol, the bullet wound being situated just in front of the left motor area. There was no loss of consciousness, although the lad fell to the ground, and shortly vomited. On the same day trephining was practised over the wound, the patient being under ether, and on removal of the bone it was found that the inner table of the skull, some hair, and a thin stripping envelope of lead had penetrated the brain. These were removed, but the main portion of the bullet could not be seen, felt, or traced. As it was thought that the bullet might have gone through the brain to the opposite side, or had dropped down, it was considered unjustifiable to grope about in the brain-substance when there was no indication or symptom as to the whereabouts of the foreign body. It was, therefore, decided to close the wound after thorough cleansing, and await symptoms, or to use the *x*-rays to localize the bullet. The patient made a good recovery, being kept on the lightest of diet. The temperature remained subnormal, and the pulse slow (from 50 to 60). When solid food was given, vomiting took place. There were pain over the left orbit and constipation. There were no paralysis and no twitching. The *x*-rays were used on two occasions without yielding the desired information, and each attempt to photograph was followed by increased headache. After six weeks the patient was allowed to get up, and was able to go about. Any imprudence or indulgence in heavy food caused a return of vomiting, eye-ache, and headache, and necessitating a return to bed and a starvation diet. At the same time slight ptosis of the left eyelid was noticed, and the face was drawn slightly to the left. Improvement continued, and after some eight months the patient was well enough to undertake a journey, in the sequence of which he had a convulsion, with loss of consciousness, after riding on a tram-car. No muscular movements were specially noticed. On returning home two or three more convulsions took place, one of them being accompanied by unconsciousness; the others were Jacksonian in character. It was said that some twitching of the left side of the face occurred, beginning in the left eye and extending to the face. The patient then rapidly grew worse, with increased headache and vomiting, slow pulse, depressed temperature, great drowsiness, and also paresis of the muscles of the left side of the face. Double optic neuritis was now observed, and it was thought that the condition was one of cerebral abscess, which was increasing in size and occasioning symptoms by pressure on the motor area. On operation an abscess was found, with the bullet within its cavity. Convalescence was eventful only owing to the cerebral hernia which formed, and which grew so large that it became necessary to slice off a portion. In three months the hernia was reduced to about the size of a peach. By the direct application in powder form of boric acid and alum daily to the brain-substance, and careful dressing and bandaging, the tumor gradually shrank, and the scalp grew until it gradually healed within another three months' time. The patient kept quite well for seven months, but one day after unusual exertion he had another fit, and following this three others occurred, one after bathing, one after vomiting, and one after measles, with a temperature of 104° F. Nine months, however, had elapsed since the last fit, and the patient was engaged in bee-farming and able to enjoy life and sports.

**Successful Treatment of Cerebellar Tumor by Trephining and Drainage.**—At a recent meeting of the Clinical Society of London, Guthrie and Collier (*Lancet*, November 4, 1899, p. 1232) exhibited a boy, nine years old, who eighteen months after operation for cerebellar tumor was in perfect health except for

blindness due to double optic neuritis. Five years before coming under observation the boy had suffered a fall on the head followed by profuse epistaxis, but had remained well for four years, when headaches came on. These grew worse, and were accompanied by drowsiness, yawning, and unsteadiness of gait. The gait was typically cerebellar; the movements of the arms, especially of the right, were ataxic; and there was double optic neuritis, with considerable impairment of vision. The tendon reflexes were normal. The patient grew progressively worse, and developed a tendency to fall backward or from side to side. The headache became more severe, and was constantly referred to the inner canthus, a feature that suggested a lesion of the right cerebellum. The grasp of the right hand became weaker than that of the left, but the left knee-jerk disappeared entirely, while the right remained active. The pulse was feeble, and the breathing became shallow, weak, and sighing. The respirations fell to from 13 to 15 a minute, and at intervals of a minute periods of apnœa occurred, lasting from ten to fifteen seconds. In the first operation the left lobe of the cerebellum was exposed, but five days later a trocar and a cannula were introduced from the right side upward, inward, and forward. About one ounce of clear, yellow, highly albuminous fluid was withdrawn. The fluid did not reduce Fehling's solution, and it was hence not considered cerebro-spinal. The patient made a good recovery, and during the succeeding eighteen months there had been no recurrence of any of the symptoms.

**Intubation in Private Practice.**—Dr. J. Trumpp (*Münchener medicinische Wochenschrift*, November 7th) draws the following conclusions: (1) Every general practitioner should strive to acquaint himself thoroughly with the technique of intubation as well as tracheotomy. (2) Intubation is absolutely indicated when the patient is in immediate danger of suffocation and there is no time for tracheotomy to be performed; it should also be done when tracheotomy is refused. (3) In other instances the physician is justified in undertaking intubation at home and in urgent cases without the necessary preparations—(*a*) when the transportation of the patient to a hospital is impossible or refused; (*b*) when the relatives and friends are told the advantages and disadvantages of the bloodless and bloody operation, and decide in favor of intubation; (*c*) when means of travel are good and the physician can reach the bedside within an hour. (4) Intubation in private practice should not be undertaken too late, because with good resisting-powers the chances of recovery are better, and the dangers all the smaller, the less the local process is advanced. 5. Inasmuch as tracheotomy in private practice is more difficult to carry out than intubation, the endolaryngeal method should be performed when the aforegoing circumstances are not fulfilled, and further, when the intubation remains useless, decubitus is suspected as the result of a continued intubation, or when in spite of every precaution the tube is frequently coughed up. (6) If tracheotomy becomes necessary, then, even in private practice, it should be performed when possible with a tube in position.

**Treatment of Obesity.**—Dr. Rud. v. Hoesslin (*Deutsche Medizinal-Zeitung*, October 26th) says that for the past five years he has adopted a combined anti-fat method which has for its basis: (1) Feeding by means of a pure albuminoid fat diet after the principle of Ebstein's anti-fat diet; (2) increase of metabolism by hydrotherapy; (3) administration of thyroid tablets; (4) increase of oxidation by increased exercise. Feeding by means of pure albuminoid fat diet has two advantages over the prescribed diet of Oertel: firstly, the quantity of food stuffs taken by the patient need not be very materially diminished; and secondly, he does not have to suffer from thirst. Another advantage of this diet is that it may be continued for a long time, even for a number of months, without in any way undermining the patient's strength or giving rise to nervous disturbances. The menu for the entire year, according to the diet principle as set down by Ebstein, is, in a word, the abstinence in so far as possible from sugar, flour—in fact, all carbohydrates; with each meal a 15-gm. piece of Seidl's bread is allowed. Dessert is cooked without sugar, but with saccharin; all sweet fruits, such as apricots, blackberries, pears, etc., as well as carrots, peas, cauliflower, are to be avoided. For breakfast coffee or tea without sugar, perhaps with saccharin, and a tablespoonful of cream, together with a piece of well-buttered Seidl's bread, are to be given. If a second breakfast is desired at ten o'clock, then the patient receives one or two soft-boiled eggs, one or two slices of fat ham or fat bologna; at four o'clock, tea or coffee without sugar. Among the drinks, Moselle wine, Bordeaux wine, water, and mineral water are allowed, but beer, even Pilsener, is not allowed under any circumstances. During the first few days, until the patient becomes accustomed to the new diet, attention must be given to the gastro-intestinal tract, since half of the patients have gastric disturbances on account of the unaccustomed fat consumption. On the second or third day mild nausea, belching, and pressure in the gastric region are often complained of. Patients soon, however, become accustomed to the diet. This diet is enhanced in its effects by hydrotherapy, in the forms of cold douches and sweat baths, which increase the metabolism. Thyroid extract is an effective help in the treatment of obesity; tablets of 0.3 gm. each are used, given once or twice daily. The pulse is observed twice daily, and if increased in frequency the dose is at once diminished or the drug is entirely discontinued. Many patients, even with small and infrequent doses, react with continuous cardiac palpitation and increased pulse frequency. In these cases the drug must be discontinued entirely.

**Neurasthenia.**—Dr. M. Wernberger (*Deutsche Medizinal-Zeitung*, October 26th) defines neurasthenia as a functional disease without any organic changes, and characterized by an increased sensibility and diminished resistance. According to Charcot, the cardinal symptoms of neurasthenia are: (1) the neurasthenic headache and head pressure; (2) disturbance of sleep; (3) rachialgia and spinal hyperæsthesia; (4) muscular weakness (amyosthenia); (5) disturbances of digestion (nervous dyspepsia); (6) disturbances of the genital apparatus; (7) psychical changes, such as irritability, fear, lack of will-power, and tired feeling after mental exertion. Secondary to these are vertigo, nervous asthenopia, hyperæsthesia, paræsthesia, fibrillary twitchings, tremor, muscular cramps, feeling of pressure, and neuralgic sensations. Of course it is rare for all these symptoms to be present; indeed, in a fully developed case of neurasthenia some of the cardinal symptoms may be absent. If increased sensibility and rapid tiredness exist, and if hysteria, dementia, tabes, and paresis can be excluded, then the diagnosis of neurasthenia is justifiable even though amyosthenia is absent. There are three degrees of neurasthenia. In the first class of cases—mild form—are included those patients who present weakness as the main symptom, a form which the laity term "nervous"; in other words, those who become excited at every noise, are tired upon arising in the morning, and only regain their elasticity, as it were, during the course of the day or at night; those who sleep poorly and complain of headache, irritability of the heart, and vertigo. The second class comprises those patients who no longer

possess the will-power and energy to overcome the inroads of neurasthenia, and thus can no longer follow their usual occupation; those who suffer from all sorts of fears, paræsthesia, hyperæsthesia, arrhythmia, tachycardia, and sometimes impotence. The third class contains the so-called severe cases, those which are on the border line of neurasthenia, so that the question arises whether we are not dealing with a development of one of the psychoses, with a "nervous apoplexy," as Müller puts it.

**Can Malarial Plasmodia be Mistaken for Nucleolated Erythroblasts?**—Dr. Engel (*Deutsche Medizinal-Zeitung*, November 9th) concludes as follows: (1) The malarial plasmodia cannot be mistaken when they contain pigment, that is, when they are old forms, inasmuch as yellowish-black pigment as it occurs in the plasmodium is never observed in the nucleus. Under these circumstances the plasmodia can be easily recognized in the fresh, unstained blood specimen. (2) The plasmodia cannot be mistaken in a fresh preparation when they show amœboid movements. Then even the spores can be diagnosticated as foreign bodies within the blood cells. (3) The plasmodia cannot be mistaken for the nucleus of the polychromatic normoblast (in stained preparations), because on the one hand the intensely stained nucleus, on the other the more or less irregular form of the polychromatic protoplasm, render error all the less likely because they resemble for the most part orthochromatic, normally stained erythrocytes. (4) The plasmodia cannot be mistaken for the small nuclei of the orthochromatic, nucleated red blood cells, as long as the nucleus is intensely stained, inasmuch as the staining of the plasmodia is very much weaker. (5) The malarial plasmodia, especially their spores, may, however, be confused with particles of nuclei, as well as with that form in which the nucleus gradually becomes smaller and disappears, as well as with that form in which the nucleus divides itself into many parts. Even the blood plaques, which seem to bear a relation to the particles of the nuclei, may occasionally be confused with the spores of the plasmodia.

**Surgical Treatment of Duodenal Ulcerations.**—Dr. Ernst Pagenstecher (*Deutsche Medizinal-Zeitung*, November 13th) says that the cause of the existence of ulceration of the duodenum has as yet not been definitely settled, but that he believes disease of the blood-vessels plays an important part. The course of the trouble is chronic—often, in fact, latent until the occurrence of severe complications; sometimes it is accompanied by marked discomfort and frequent small hemorrhages which may be evacuated either per os or per rectum. The indications for surgical intervention are: (1) perforation of the ulcer; (2) recurrent severe hemorrhages; (3) increased cachexia, which is dependent upon the presence of the ulcer. In all cases of perforative peritonitis it is well to think of the possibility of a perforating duodenal ulcer, and to try to close the opening, if it exists, with sutures; unfortunately, in spite of all the result is often uncertain. Excision of the ulcer is to be undertaken only in the rarest of cases. When the indication is to relieve the severe symptoms dependent upon the ulcer, gastro-jejunostomy is advocated, and in one severe case it gave a brilliant result. It is possible, though of course not certain, that after a rest of the affected duodenum a healing of the ulceration, not only in the functional but also in the anatomical sense, may take place. As far as concerns the duodenal stenoses which are secondary to the old ulcerations, it must be determined whether the stenosis exists above or below the papilla; in the latter instance it is often combined with disease of the biliary ways, which gives rise to stagnation and may cause icterus. In some instances a narrowing may take place without any preceding cicatrix; bands in the neighborhood of the ulcer narrow the lumen of the duodenum.

**Seborrhœa of the Body (Duhring) and its Relations to Psoriasis and Eczema.**—In a study of body seborrhœa in its various relations, Török (*Archiv für Derm. und Syphilis*, lvii., 1899) endeavors to demonstrate that the affection is only an extremely attenuated form of psoriasis, and not related, as has been recently claimed, to Unna's seborrhœic eczema. In conclusion the writer thinks he is authorized in saying: (1) The existence of the most important macroscopic and microscopic lesions of psoriasis permits us to unite in a single group all the typical and atypical cases of psoriasis, starting with the cases typical in their symptoms, course, and localization, and ending with the slightly developed forms, such as those which have become irritated, eczematized, etc., including the rebellious cases and those which disappear readily or have an atypical localization. Neither clinical observation nor anatomo-pathological examination permits the discovery of a close connection between psoriasis and eczema, and this is just what we should expect if we are to look upon eczematization as a mode of reaction of the skin following irritations. (2) We must consider seborrhœa of the body (Duhring), lichen annulatus serpiginosus (Wilson), as a variety of psoriasis vulgaris less intense in degree and having an atypical localization.

**Necrotic Acne.**—In a laboratory work carried out with Dr. Amabilis of Mexico, Dr. Sabourand (*Annales de Dermat. et de Syph.*, October) presents the following conclusions: 1. Necrotic acne is a perifolliculitis of the upper portion, with extension at the same time superficially and into the deeper parts, terminating in necrosis of all tissues invaded and in a depressed variola-like cicatrix. 2. The lesion exacts for its centre a follicle previously infected by the micro-bacillus of fatty seborrhœa. 3. This affection is produced by a yellow staphylococcus, whose presence in a pure state is constant and abundant in the lesion from beginning to end. 4. This staphylococcus is not to be distinguished by present methods of technique from the common staphylococcus aureus. 5. This fact taken in connection with the attentive observation of the various clinical forms of necrotic acne tends to bring into the same group (1) the peri-papillary impetigo of Bockhart; (2) impetigo pilaris of the adult; (3) true necrotic acne. While the treatment of an acute outbreak is simple, usual methods are absolutely powerless to prevent recurrences. In reality the treatment of recurrent necrotic acne runs into that of micro-bacillary fatty seborrhœa, which is its constant and indispensable substratum.

**Leptothrix Infection.**—Max von Arx (*Correspondenz-blatt f. d. Schweizer-Aerzte*, 1899, Nos. 6 and 7) reports three cases of phlegmon of the neck, all very serious, which came under his observation together with a case of Nielhau's of similar origin. All of these cases began with the extension of the inflammation due to carious teeth, and resembled one another furthermore in that their clinical history and progress were alike. They were readily distinguished from other forms of inflammation. The progress of the infection was slow; the swelling and infiltration were very marked, the latter being very extensive, in one case almost reaching the umbilicus. On incision very little pus was found; instead there was an offensive fluid which gave off a very disagreeable odor. The soft parts were unhealthy and grayish-white; the microscopical examination showed leptothrix, together with other bacteria.

As to prognosis, von Arx declares that unless early multiple incisions are made, relieving the congestion as well as freeing the contents of the phlegmon, a fatal issue may be expected. Wet antiseptic dressings are to be preferred to those that are merely aseptic. The proper care of the teeth affords the best prophylactic.

**Hæmatoporphyrinuria.**—Ruedy (*American Journal of Insanity*, October, 1899, p. 326) reports a case of hæmatoporphyrinuria following the use of trional, and expresses the opinion that the condition occurs occasionally in association with a number of different pathological conditions, and even physiologically; more frequently in association with hemorrhage into the alimentary canal and in cases of lead poisoning; and finally after the use of sulphonal and allied substances. As a diagnostic and prognostic sign it is of little value, except in connection with sulphonal poisoning, when it becomes of grave prognostic import, especially in women. The origin of the condition may not always be the same, and in cases of sulphonal intoxication it seems to be associated with badly damaged renal epithelium, probably of a secondary nature. The condition is one that is more easily prevented than cured.

**Oysters and Their Possible Dangers to Health.**—Professors Herdman and Boyce, in their report contained in a "Memoir of the Lancashire Sea Fisheries," have been investigating the cause of the color present in the green oysters, and our own much-prized and world-renowned Blue Point has come in for a share of their scrutinizing attention. The green hue is equally familiar to the man who raises them for the market, to the one who raises them from their bed with a pair of rakes, and also to him who raises them out of their own juices on the half-shell by means of a silver trident. This coloring has been attributed variously to metals, vegetable coloring-matter, bile pigment, and the pigment of diatoms. The investigations recently carried on show, according to an editorial in *The Lancet* of November 18th, on "Oysters and Disease," that in point of fact the green color is not always due to the same cause. In one variety it is copper, and this appears true of the American green oyster, but the metal is found in association with green leucocytes. In other varieties iron is found, while a diatom or moss is suspected as a cause in still others. We are told that American green oysters are frequently thin and have shrunken livers. The important part of the report deals with contamination of oyster beds by sewage and the results of experimental feeding with the fæces of typhoid patients. Oysters taken from the neighborhood of discharging sewers showed abundant bacteria in the fluid of the pallial cavity and also in the rectum. In fæces-fed oysters the typhoid bacillus could be cultivated from the fluid of these cavities, fourteen days after infection. Bacilli of the colon group were frequently found in oysters supposed to be contaminated by sewage. The recommendation is made that oyster beds from which markets are supplied be kept free from possible contamination of this kind.

**Fractures and Other Injuries of the Child during Delivery.**—Dr. David Jessup Doherty, in the *American Gynæcological and Obstetrical Journal*, November, states that the indications for version are of three classes: I. Those conditions which demand rapid delivery: (1) eclampsia; (2) concealed hemorrhage; (3) placenta prævia. II. Conditions which simply jeopardize the child's life: (4) face and brow presentations, (5) prolapsus of the funis, (6) prolapse of the arm or foot alongside the head. III. Conditions which may make unaided delivery improbable: (7) high arrest from inertia uteri, large head, constriction of uterus, Bandl's ring, or rigid soft parts; (8) pelvic deformity; (9) transverse presentation. In only two of these conditions, viz., 1 and 2, is it necessary that extraction should follow version; in 3 complete version is sufficient to stop hemorrhage, and in others either forceps may be used instead of version, or version may be avoided by suitable measures. In short, extraction should not follow version if the mother and child are doing well, if the funis is all right, and if the presenting breech is not too blue. The completion of the delivery should be left to nature. But, if extraction must be made, the following points are suggested: (1) Traction should be made intermittently, at regular intervals or during the pains. (2) It should be supported by external suprapubic pressure by an assistant. (3) The hands should grasp the fœtal parts as near the vulva as possible. When grasping the feet, the heels should lie in the hollow of the hand, the middle finger inserted between the two tibiæ and the other fingers outside the fibula. In grasping the legs the thumbs lie parallel along the calves and the fingers along the internal surface. (4) There should be no twisting, and the direction of traction should be downward and backward until the anterior hip is visible, then horizontally with lever movements to lift the posterior hip over the perineum, and then again backward to free the anterior hip. (5) The blunt hook should never be used on the living child. Happily forceps are no more made with one handle terminating in a hook. (6) In liberating the extended arm it should be grasped as near the wrist as possible, because it will thus be more easily flexed at the elbow; it would be a serious error to grasp it between the shoulder and the elbow. (7) Sweeping the arm over the back is rarely necessary, but if it is, the humerus should be rotated inward. (8) The finger should never be inserted in the axilla to help out the shoulder. A soft catheter would be better, but he feels sure that interference is wrong, for if the head has passed through the shoulders must necessarily do so. If one has not the patience to wait, changing the position of the mother to the side corresponding to the infant's back may help to dislodge the shoulder. (9) In breech presentation the forceps is required, is safer, quicker, easier than any other method. (10) Patience is the best of all forceps.

**Blastomycetic Dermatitis.**—In the *Annals of Surgery*, November, Drs. Owens, Eisendrath, and Ready, of Chicago, report another instance showing the relation of blastomyces to neoplasms, and review the literature of the subject, including the cases reported by Gilchrist, Stokes, Wells, Hersler, Hyde, Hektoen, and Bevan in this country. The patient in question was a woman thirty-eight years of age, who presented an ulcer eight by four inches in size upon the antero-internal lateral aspect of the lower third of the thigh. Four years previously a circumscribed painful elevation with irregular surface had appeared in this same locality. This opened spontaneously, discharging a yellowish fluid. Seven months later the ulcer was the size of a hen's egg. Worm-like bodies as thick as a hair-pin could be squeezed out. The ulcer gradually increased in size until it was removed in April, 1899. The general appearance was "seedy," or coarsely granular, and the surface lacked the redness of normal granulation tissue. The worm-like bodies were supposed to be papillary pus casts. As a whole the lesion suggested lupus, especially as there was no lymphatic involvement. The operation wound healed with the aid of skin grafts, and the patient was discharged in July. The organisms found on histological examination are shown in a number of well-

executed drawings. The great variation in the size of the organisms found seems to depend largely upon the culture media in which they develop. The smaller forms are buds detached from the mother cell. Mafucci and Sirleo, who are less enthusiastic than some other of the Italian scientists with regard to the part played by blastomyces in the production of malignant tumors, still do not exclude this possibility, and believe that no experimental proof has been put forward that carcinoma or sarcoma can be caused by them.

**Inguinal Hernia in the Young.**—Dr. R. H. Russell (London *Lancet*, November 18th) describes the operation which he employs in curing inguinal hernia in the young as follows: The incision is made in the groin parallel to Poupart's ligament; the cord is sought for, the coverings of the cord are successively opened, and the cord, the sac, and the testicle are drawn out of the scrotum. The vas deferens and the vessels of the cord are next defined and separated from the sac, and the sac is freed from these structures as high up in the canal as possible. Chromicized catgut ligature is now applied to the neck of the sac in the form of a Staffordshire knot, and the sac is removed. The superfluous coverings of the cord are cut away, and the testicle is carefully washed and dried and replaced in the scrotum. The wound in the groin is closed by the subcuticular mode of suturing, a single thread of silkworm gut being used for this purpose, the two ends of which emerge from the skin about one-half inch from either extremity of the wound. A single layer of gauze and collodion is then applied to the wound, and when this is sufficiently dried a pad of dry dressing is bandaged on over all. The child, if a small one, is placed on a double long splint, to which it should have been accustomed for a day or two before the operation. At the end of a week the silkworm-gut thread is withdrawn without disturbing the collodion and gauze, and a day or two later the child may be allowed to run about. To recapitulate the salient features of this procedure, the operation consists simply of removal of the sac and nothing else; the walls of the canal are untouched by the knife and they are not sutured in any way; there is no after-dressing of the wound, and there is no prolonged period of recumbency such as is almost invariably insisted upon by authors. In young children it is quite unnecessary to incise the external oblique aponeurosis; the neck of the sac can easily be pulled outside the external ring, so that when the stump is allowed to go back it passes up at once well within the curved fibres and becomes flush with the rest of the parietal peritoneum. As to the age for operating, his rule is not to operate by choice on any child under twelve years of age.

**The Present Uses of Excision of the Knee-Joint.**—Dr. Howard Marsh (London *Lancet*, November 18th) maintains that the cases in which excision, with few exceptions, is advisable are limited to adults and adolescents in whom the growth of the limb is, or is nearly, complete, and the bones have acquired so firm a texture that after the operation they readily undergo an unyielding synostosis. Such cases may be arranged in the following groups: Group 1. Those cases in which the joint has become fixed in a position of deformity. The majority of such cases are tuberculous, but others are the result of septicæmia occurring in a variety of circumstances; of the gonorrhœal arthritis; of the form of disease placed below in group 3; of some forms of osteo-arthritis, etc. In this group operation is resorted to for the purpose of removing deformity. Group 2. Those cases in which the joint is incapacitated by incomplete ankylosis resulting usually either from tuberculosis or septicæmia. The tuberculous cases are those in which, by chronic inflammation, extending it may be over several years, the synovial membrane, ligaments, and cartilage have been destroyed and replaced by fibrous adhesions, which, while limiting to a great extent, do not entirely prevent, movement. Under these circumstances the joint remains irritable and painful when the adhesions are stretched by exercise, and the patient is prevented from following any active employment. In other cases the disease has commenced in the articular end either of the femur or of the tibia, and has resulted in the formation of a circumscribed deposit of tubercle in the immediate vicinity of the joint, upon which it acts as a constant irritant. In other cases, the joint has been destroyed by quiet and slowly advancing tuberculosis. In septicæmic cases, as in tuberculosis, the condition present is that of incomplete fibrous ankylosis leading on exercise to irritability and pain. Group 3. The group of cases in which excision may be required is that in which, by a process recurring of which very little is at present known, a variable number of joints, one after another, become inflamed, slightly over-warm, and somewhat painful, and then, in the course of a few months, become fixed by complete bony ankylosis in the position of flexion. Group 4. When, as the result of osteo-arthritis, any joint has undergone extensive structural change, there are one or two conditions in which excision may be performed alike with safety and great advantage to the patient: first, when the ligaments have become weakened and relaxed so that the joint is reduced to a loose, almost flail-like condition; and secondly, when the joint has become fixed at such an angle of flexion that the limb is useless.

**Report of Cases of Sudden Death from Pulmonary Embolism following Injuries or Operations upon the Pelvic Region.**—Dr. George P. Biggs (*New York Medical Journal*, November 25th) gives the following brief conclusions which were drawn from a study of a number of cases: (1) Emboli are usually in the shape of cylinders, a little smaller than the lumen of the vein in which they form. Such cylinders often become folded several times upon themselves as they are forced into the branches of the pulmonary artery. (2) The thrombi formed in the veins are chiefly of the red variety, though occasionally they are mixed. They may be quite firm and slightly stratified, though at times, to the untrained eye, they differ but little from post-mortem coagula. (3) Once started, thrombi in the veins tend to grow rather rapidly in the direction of the blood current. (4) At the best, the thrombi are but loosely attached to the wall of the vein, and may separate completely, leaving no distinct mark indicating the area of attachment, as was the condition in two of the cases reported. (5) A long, cylindrical thrombus may have but a very small base of attachment to one side of the vein, while the remainder of the thrombus floats free in the blood. This explains the absence of symptoms of venous obstruction. (6) While infection may sometimes play an important part in the causation of these thrombi, such does not usually appear to be the case. It seems probable that simple extension of thrombi formed in the smaller veins, damaged at the time of operation or injury or by subsequent inflammation, will explain the occurrence of thrombi in the large neighboring veins. Slowness of venous circulation naturally favors this process.

**A Short Umbilical Cord as a Cause of Dystocia.**—Dr. Samuel M. Brickner, in the *American Journal of the Medical Sciences*, November, briefly summarizes the diagnostic points in the order of their importance as follows: (1) Recession of the head in the inter-

vals of pains; (2) Arterial bleeding during and between uterine contractions, (3) Urination in small quantities in the intervals of pains after the establishment of the second stage; (4) Pain over the placental site, especially during a uterine contraction or during the application of the forceps, (5) A desire of the patient to sit up; (8) Uterine inertia. Treatment: It is unfortunate that a diagnosis of an absolutely short cord can rarely be made with certainty before birth of the child as far as the umbilicus. If it were possible always to make sure of the condition treatment would be of little avail. When a short cord is suspected, and the life of the child is thought to be in danger from the objective signs of an accelerated heart or the passage of meconium, the labor should be terminated as soon as possible. By pressing the fœtus down the placental insertion of the cord is brought near its umbilical insertion, and the danger of rupture is somewhat obviated; but this is not always feasible or possible. Postural methods may be tried by having the mother assume a squatting or kneeling position, as recommended by Denman and praised by King. If the child presents by the breech, the cord should be tied as soon as the umbilicus is born. The advice given in some text-books, to tie the cord regardless of the position if it is found too short to allow birth to take place, is little short of absurd. The impossibility of tying the cord of the child in the second stage of being born is so self-evident that it seems almost laughable to refer to it were it not a fact that some of the authors recommend it in perfect good faith. The use of the forceps is practically contraindicated in these cases; it would be almost certain to end disastrously to the child.

**The Influence of Physical upon Mental Disease.**—Dr. W. J. Handfield Haslett (*Indian Medical Record*, November 1st) formulates his conclusion to an interesting article upon this subject as follows: That febrile, suppurative, painful, and constant diseases are most likely to produce benefit, particularly boils, carbuncles, erysipelas, and some of the specific fevers; that protracted and debilitating and wasting diseases, producing anæmia and loss of blood, rarely produce any mental improvement; that purely convulsive neuroses are rarely capable of any amelioration in this way; that stuporose mental states and the second stage of acute attacks are most readily influenced for good; lastly, that the evidence chiefly points to the influence being produced by unwonted afferent impulses by abnormal peripheral irritation.

**The Nutritive Value of Albumose Peptone.**—Dr. A. E. Austin (*Boston Medical and Surgical Journal*, November 30th) believes that it is conclusively proven: (1) that it is impossible to maintain life upon peptone alone, as it is upon all other strictly nitrogenous foods; (2) that, upon the addition of a small amount of carbohydrate, the nitrogenous loss from the body, with the slight amount of albuminous food, is very much retarded; (3) peptone must be regarded as not only able to replace albumin as a means of checking nitrogenous loss, but also as a means of increasing albuminous tissue; (4) That, for a period of forty-five consecutive days, at least, peptone causes no diarrhœa or disturbances of the stomach.

**Hæmophilia.**—Dr. G. W. Wagner (*Physician and Surgeon*, September, 1899) draws the following conclusions: 1. That hæmophiliacs make blood rapidly, the cause of which is undetermined. 2. There is a tendency to plethora of the smaller vessels, especially of the capillaries. 3. That the deficiency of oxygen in the blood is one of the main reasons for its slow coagulation. 4. That the narrow lung space, at least in some cases, is a factor in the deficient oxygenation of the blood and would suggest that in future the capacity of the lung space be carefully noted. 5. Apparently the best remedy to control the hemorrhage is oxygen either by inhalation or contact. It acts in two ways: it causes greater rapidity in the coagulation of the blood, and it also causes the nuclei of the endothelial cells of the capillary wall to swell and so narrow the lumen of the vessel.

**Lipæmia, Fat Embolism, and Thrombus in Diabetes.**—Ebstein (*Virchow's Archiv*, 155, p. 571, 1899) describes an interesting case of a domestic servant who had been apparently cured of a severe attack of diabetes, when she suddenly collapsed and died of typical diabetic coma. On autopsy there was found a condition of lipæmia together with fat embolism of the lungs, kidneys, and cerebral vessels. There were demonstrable fat masses in the arteries themselves, parenchymatous inflammation of the kidneys, spleen, and liver, and diffuse fatty infiltration of the mediastinum. The percentage of fat in the blood was far above the well-known physiological limits. Ebstein maintains the hypothesis that the fatty degeneration of the different tissues of the body gives rise to the extra formation of the fat globules, which accumulate until they are of sufficient size to occlude some vessel.

**Meningitis.**—Dr. James Barr (*British Medical Journal*, November 18th) writes as follows: "The following methods of treatment are applicable to tuberculous and all the forms of simple meningitis, even including cerebrospinal fever. There is no disease in which antipyretic treatment requires to be more thoroughly and efficiently carried out. Of all the means at our disposal for this purpose I prefer a large ice-cap formed of Leiter's tubing, with a constant stream of cold water flowing through it, applied to the shaven scalp. The application of cold to the head not only lowers the general temperature, but also moderates the circulation within the cranium. This latter statement is perhaps opposed to the researches of Dr. Leonard Hill, who denies that there are any vasomotor nerves supplied to the cerebral vessels, and maintains that the cerebral circulation is kept up by the splanchnic area. This latter statement is no doubt in the main true, but it does not necessarily follow that there is no local regulative nervous mechanism of the cerebral circulation. We all know that a large dose of nitrite makes one feel as if the top of the head were coming off. I recollect once in a case of granular kidney an attack of hemiplegia which I ascribed to one-sided spasm of the vessels supplied to the motor cortex; the hemiplegia was removed by a few doses of nitro-glycerin. I highly appreciate the valuable work of Dr. Leonard Hill, but I am not bound to accept all his conclusions. However, supposing his views all ultimately established, we can still explain the beneficial action of the ice-cap by its effect upon the general circulation. In many cases this local application of cold is not sufficient to keep the general temperature down to a fairly normal level; in that event I apply cold compresses to the abdomen. The application of cold to the splanchnic area raises the general arterial pressure, but this has a beneficial effect on the cerebral circulation by heightening the velocity without necessarily augmenting the transudation from the vessels. The temperature is usually easily controlled in meningitis, but if there should be any hyperpyrexia it can be quickly reduced by swinging the patient in a hammock and running a small stream of cold or tepid water over the body. The cold to the head should be continued until the general temperature has been for some time subnormal, and if any pyrexia should afterward occur it should be immediately combated by resort to the ice-cap."

New York, December 23, 1899.

## GENERAL PERITONITIS AND ITS TREATMENT.

THE subject of the treatment of general septic peritonitis is always one of interest, although we know that we are almost invariably fighting a losing battle. One of the commonest causes of this as well as other forms of peritonitis is disease of the vermiform appendix, so that we are thus able to speak properly of a form of appendicular inflammation with general peritonitis, characterized by a set of symptoms whose presence almost at once destroys hope in the mind of the surgeon. Cases are reported from time to time, of recoveries from this condition after operation with extensive peritoneal irrigation, usually with surgical salt solution and subsequent free drainage. The method is not entirely satisfactory even when successful, and the results are not always to be accepted without reserve as cured cases of general septic peritonitis, because it is often the case that a very considerable fraction of the peritoneum is not involved at all in the disease, in spite of clinical appearances, and may even have escaped contact with the irrigating fluid used at the operation. One of the most unsatisfactory parts of the question is that concerning safe and efficacious drainage. The rapidity with which peritoneal adhesions form around such a focus of irritation as that caused by a strand of gauze packing is well known, but the effect of this process upon the perviousness of the drain has perhaps not received the attention it deserves. The aim of the operator has always been to remove as much as possible of the inflammatory products by irrigation, and to provide then efficient drainage for a period of at least forty-eight hours. It has been recognized that it is not possible to disinfect the peritoneal cavity, but there has always been hope that the peritoneum would be left in a condition to cope with the remaining infectious matter, and would take care of any new septic products which might be formed. The peritoneum has been trusted to great lengths in this regard by some operators, and in some cases after free irrigation with salt solution and local cleansing of the site of infection, the abdomen filled with hot salt solution has been entirely closed. Successes have been reported after this method, though we hesitate to say in consequence of it, for the question of the actual extent of peritoneum involved is not always easy to settle, though this has an important bearing on the future of the case. If the peritonitis is actually general, the alexic function of the whole peritoneum is practically lost, and we should be justified in thinking that mere dilution of the poison would not prevent its entrance into the circulation. Furthermore, we must remember that by the time a true general peritonitis has developed, the human organism must already have absorbed a considerable quantity of toxins which have begun their harmful work on the nervous centres with great promptness. In cases in which, at the time of operation, although clinically having every evidence of general peritoneal involvement, we find, in consequence of the lack of the customary adhesions, coils of more or less uninvolved intestine, the possibilities of a favorable manifestation of the protecting power of the peritoneum are very considerable, and it is under such circumstances, we think, that most of the so-called cases of general peritonitis are cured.

We must remember that there are several elements in cases of general peritonitis which add to and in fact constitute the basis of the gravity of the disease, besides the condition of the peritoneal membrane itself. There is more to do in fighting this disease than simply to remove the inflammatory products in the peritoneal cavity, and to prevent their reaccumulation. Tympanites from intestinal paresis, with the consequent absorption of toxins from the putrefying intestinal contents, is a very serious element in the disease, dangerous and unsatisfactory to treat. If this condition is well developed, it would be impossible to put any quantity of salt solution into the abdominal cavity and then close the wound. The consensus of opinion at present in regard to the disease under consideration seems to be that it is almost impossible to save a case of general peritonitis, and that our chances of success by what are now commonly accepted methods of treatment are inversely proportional to the extent of peritoneum involved. Surgeons are apparently pretty well agreed that it is best not to resort to general abdominal irrigation, if possible, and that in any case the cleansing of the peritoneum shall first be undertaken carefully and methodically from the point of infection outward. If we can ever have an apparatus to supply hot salt solution continuously, and thus establish the same system that has been used in joints, we might save some otherwise hopeless cases of general peritoneal inflammation; but, until we can, the weight of the evidence seems to be that there must be some provision for drainage.

## WHY IS THE NEGRO BLACK?

IN *Pediatrics* about a year ago a vehement discussion was raised by the publication in the editorial columns of that paper of the statement, made on the authority of a French physician, that negro babies when born were of a pinkish hue; in fact, differed little if at all in color from infants born of white parents. This expression of opinion was strongly rebutted by physicians in the South, who with unanimity declared that

they had never seen a baby, born of black parents, white at birth. *The Lancet* in Great Britain took the matter up, as well as many medical journals on this side, and although their correspondents were all of one mind as to the negro progeny when born not being white, yet, curious to say, there was a considerable divergence of views with regard to the exact tint. The truth is, that all newly born negro infants are not of quite the same color, but vary to a certain extent. However, the assertion of the French physician that they are of a delicate pinkish hue was totally disproved.

Anthropologists and men of science have for long wrestled with the problem with respect to the cause of the color of the black man. Men of religion hold that it is owing to the curse of his father falling upon the descendants of Ham. Some think that the negro is a distinct race whose color has been the same since the world was first peopled, while again others contend that the human people were all originally of the same color, and that the change has been effected by the influence of the climate of the countries in which they have lived.

The question is dealt with in an interesting manner by a writer in a journal named *The Family Doctor*, who says: "Though children in tropical climates may be born apparently white, of parents whom the solar heat has darkened in hue, and though we have not the means of ascertaining that white nations exposed in tropical climates for ages do become darker, still, in conformity with the well-known law of the transmission of hereditary mental qualities, parents so blackened can communicate a slight, though imperceptible tinge to their offspring, who will thus enter upon existence with a larger share of black than their parents, and if equally exposed themselves will convey more to the next generation. Thus the black tribes of Africa may have become so through a long succession of ages, while the more recently peopled countries of tropical America exhibit the process in a comparatively early stage. It is needless to present, in opposition to this theory, that no change has been observable since the discovery of America, for the ages required for the process must have been analogous to those required for geological phenomena, and are not to be squared with our usual ideas of time. All the variations in the external appearance of man, however, cannot be referred to the influence of the solar heat, though, before mentioning other causes, we may point out another clear instance of its action. In the cases of the aborigines of Hindostan, who are somewhat browned in complexion, the action of the climate is clearly observable, which is proved by the circumstance of the female inhabitants of the harem, derived from the same stock, being generally fair in hue. This is unquestionably in consequence of their secluded life, which prevents that exposure of person which their relations of the other sex necessarily undergo. And indeed, were color the only point to be considered, the doctrine of the action of climate might be held to be the best means of accounting for the wide varieties of the human species. . . . Whatever may be the immediate or remote causes of the dark complexion of the negro, philosophical inquiry has shown us that to him it is a provision of nature, mercy, and benevolence. . . . The black color of natives of tropical regions may justly, then, be considered as a wise experience provided by Omnipotence for cooling the fever of the blood under the influence of the scorching sun."

This theory is at least as plausible as any other, but taking the fact into consideration that the problem as to why the negro is black is impossible of definite solution, a discussion of the subject is, although interesting, perhaps somewhat useless.

## THE LIABILITIES FOR THE TREATMENT OF PATIENTS IN PAY HOSPITALS.

In the suit of Ward against the St. Vincent's Hospital, in this city, previously noted in the MEDICAL RECORD (August 12, 1899), to recover damages for burns due to the careless use of a hot-water bag by a nurse, the jury before Judge Leventritt failed to agree on a verdict. It will be recollected that this case was the subject of a decision in the appellate division of the supreme court several months ago regarding the liabilities of hospitals in their treatment of pay patients.

The following is the text of the ruling made at that time. "Though the defendant is called a charity hospital, it has its pay side, on which side it is in the habit of furnishing private rooms and nurses to well-to-do persons for a full price, thus entering into an express contract. For the breach of that contract the plaintiff is entitled to the same damages as though the action had been for negligence pure and simple, and she is entitled to an adequate compensation for her injuries. The person furnished (Miss Kinney) was not a trained nurse, but a pupil in the defendant's training-school, having studied only nine months of the two years required for the course. It stands to reason that such a misfortune as happened to Miss Ward would have been less likely to occur had she been in the hands of a fully trained nurse. It is for the jury to say whether, in furnishing this careless pupil, of limited experience, the defendant fulfilled its contract obligation to the plaintiff; and if it did not, and injury resulted from the breach of the contract, to award the adequate compensation for such injury."

The principle upon which such an opinion was rendered was based upon the assumption that whenever there is a question of money in a given transaction, the damages are necessarily decided by a strictly pecuniary standard. While this must be admitted in all fairness and on strict business principles, an exactly opposite condition applies to exclusively charitable institutions. When gratuitous service is rendered, the recipient, who is the only person benefited thereby, must take them at his own risk. Pure charity simply accepts the results from both points of view without bargaining to control them.

While we congratulate the hospital in question on

its escape from heavy damages by reason of disagreement of the jury, there is no assurance in the future that the case in question will in any sense govern other similar ones that may come before the courts.

In the last trial particular stress was laid upon the charity side of the hospital's work, which was eminently proper so far as it went, although it was made equally evident that the money element in the transaction implied a pecuniary penalty for breach of contract. It was not a question of proper motive on the part of any of the persons concerned, but simply an implied accountability for a preventable accident. It was also contended that the contracting party was responsible for the acts of all helpers under its control. Fortunately for all similar institutions, this is still an open question, and will tend at least to discourage many annoying suits against them which, for the most part, are founded on trumped-up charges, and are abetted by designing sharpers, arrant frauds, and shystering lawyers. No matter in what light the present verdict may be viewed, the lesson is plain enough to all. The safe side is evidently the strong side. It should be the aim to avoid all cause for complaint in any and every direction. It is not what we may escape, but what we may prevent.

## News of the Week.

**Marine-Hospital Service Examinations.**—A board of officers will be convened at the Service Building, 378 Washington Street, New York City, Wednesday, February 7, 1900, for the purpose of examining candidates for admission to the grade of assistant surgeon in the United States Marine-Hospital Service. Candidates must be between twenty-one and thirty years of age, graduates of a respectable medical college, and must furnish testimonials from responsible persons as to character. The following is the usual order of the examination: 1, physical, 2, written; 3, oral; 4, clinical. In addition to the physical examination candidates are required to certify that they believe themselves free from any ailment which would disqualify for service in any climate. The examinations are chiefly in writing, and begin with a short autobiography of the candidate. The remainder of the written exercise consists in examination on the various branches of medicine, surgery, and hygiene. The oral examination includes subjects of preliminary education, history, literature, and natural sciences. The clinical examination is conducted at a hospital, and when practicable candidates are required to perform surgical operations on a cadaver. Successful candidates will be numbered according to their attainments on examination, and will be commissioned in the same order as vacancies occur. Upon appointment, the young officers are, as a rule, first assigned to duty at one of the large marine hospitals, as at Boston, New York, New Orleans, Chicago, or San Francisco. After five years' service, assistant surgeons are entitled to examinations for promotion to the grade of passed assistant surgeon. Promotion to the grade of surgeon is made according to seniority, and after due examination as vacancies occur in that grade. Assistant surgeons receive $1,600, passed assistant surgeons $2,000, and surgeons $2,500 a year. When quarters are not provided, commutation at the rate of $30, $40, or $50 a month, according to grade, is allowed. All grades above that of assistant surgeon receive longevity pay, ten per cent. in addition to the regular salary for every five years' service up to forty per cent. after twenty years' service. The tenure of office is permanent. Officers travelling under orders are allowed actual expenses. For further information, or for invitation to appear before the board of examiners, address the Supervising Surgeon-General, United States Marine-Hospital Service, Washington, D. C.

**The Antivisection Bill Again.**—Dr. W. W. Keen, of Philadelphia, as president of the American Medical Association has issued the following appeal: "To the members of the medical profession in the United States: The cause of humanity and of scientific progress is seriously menaced. Senator Gallinger has again introduced into Congress the bill 'for the Further Prevention of Cruelty to Animals in the District of Columbia,' which he has so strenuously and misguidedly advocated in the last two Congresses. Its present number is 'Senate Bill No. 34.' Twice the committee on the District of Columbia has also unfortunately and misguidedly reported the bill with a favorable consideration. The bill is speciously drawn to seem as if it were intended only in the interest of prevention of cruelty to animals. The real object of the bill is twofold: First, to prohibit vivisection, and, secondly, to aid the passage of similar bills in all the State legislatures. I need hardly point out to you that this would seriously interfere with or even absolutely stop the experimental work of the Bureau of Animal Industry and the three medical departments of the government, the army, the navy, and the Marine-Hospital service. The animals themselves might well cry out to be saved from their friends. No more humane work can be done than to discover the means of the prevention of diseases which have ravaged our flocks and herds. All those who raise or own animals, such as horses, cattle, sheep, pigs, chickens, etc., are vitally interested in the preservation of their health and the prevention of disease. The inestimable value of these scientific researches as to the prevention and cure of disease among human beings it is superfluous for me to point out. Modern surgery and the antitoxin treatment of diphtheria alone would justify all the vivisection ever done. As my attention has been called officially to the introduction of the bill, I take the opportunity of appealing to the entire profession of the country to exert themselves to the utmost to defeat this most cruel and inhumane effort to promote human and animal misery and death and to restrict scientific research. It is of the utmost importance that every physician who shall read this appeal shall immediately communicate especially with the Senators from his State, shall also invoke the aid of the Representatives from his or other districts in his State, and

by vigorous personal efforts shall aid in defeating the bill. It is especially requested also that all of the national, State, and county societies at their next meeting take action looking toward the same end. If regular meetings are not soon to be held, special meetings should be called. Correspondence is invited from all those who can give any aid. The committee on the District of Columbia consists of Senator James McMillan (Michigan), chairman, and Senators J. H. Gallinger (New Hampshire), H. C. Hansborough (North Dakota), Redfield Proctor (Vermont), J. C. Pritchard (North Carolina), Lucien Baker (Kansas), C. P. Wetmore (Rhode Island), C. J. Faulkner (West Virginia), Thomas S. Martin (Virginia), William M. Stewart (Nevada), and Richard Kenney (Delaware). Personal letters may be addressed to them or to other Senators. Petitions should be addressed to the Senate of the United States."

**Drs. William Osler and Howard Kelly,** of Baltimore, have been elected honorary members of the Royal Academy of Medicine of Ireland.

**Glanders in New York.**—There have been a number of cases of glanders in this city during the past month, but the health board officials have been watching them carefully, and it is believed that there is no danger of an epidemic. The disease made its appearance about four weeks ago in a stable on St. Nicholas Avenue, where fifteen horses developed symptoms of the disorder. All were promptly killed and their carcasses burned, together with their stalls and bedding.

**Electrical Executions.**—At a recent meeting of the Society of Medical Jurisprudence, in a paper read by Roger M. Sherman on "The Law and Science of Capital Punishment by Electricity," it was contended that death by the method now used in this State has not been proved as yet to be instantaneous, and that, if not instantaneous, it was cruel. The speaker believed that the dynamo would eventually give way to the axe.

**A Suit for Medical Services.**—About a year ago a wealthy resident of Cortland attempted suicide in the village of McLean, but failed to accomplish his object, and repenting called in a physician. The latter rendered all necessary services, both medical and surgical, and saved the man's life. Later the physician sued his patient for $10,000, claiming that the man's life, which he had saved, was worth that amount. The claim of $10,000 was not allowed, but the plaintiff was awarded $900.

**An Alleged Grave Robbery.**—A prominent physician in New Haven, and a member of the faculty of the Yale Medical School, was charged recently with robbing a grave. A dispensary patient, a girl, thirteen years old, died, and, the case having been a peculiar and puzzling one, an autopsy was requested. The parents would not consent, however, and even refused an offer of a considerable sum of money for permission. It is alleged that the physician then hired an undertaker to disinter the body and take it to his warerooms, where the autopsy was to have been performed, the body then being returned to the grave. The father's suspicions had been aroused, however, and he set a watch on the grave, with the result of detecting the removal of the body.

**Medical Matters in the South African War.**—In the nine weeks since the Boer ultimatum was delivered there have been twelve engagements, with losses to the British in killed, wounded, prisoners, and missing, but not including deaths from disease, of a total of 7,630. Over three thousand of this number occurred during last week in the three disastrous battles of Generals Gatacre, Methuen, and Buller. A son of General Lord Roberts was wounded in the last engagement, and was operated upon by Sir William MacCormac, but died of his injuries. Typhoid fever prevails at Ladysmith, thirty-two cases of the disease being reported by General White on December 12th. Nearly all of the officers and about seventy per cent. of the men were inoculated against typhoid fever before leaving England or during the voyage. The London correspondent of the New York *Times* complains that no preparations have been made in England for the care of the returning wounded and invalided soldiers. "Already," he says, "the wounded from our hosts in the field are streaming back again in miserable plight, and no preparation has been made for their reception. Convalescent hospitals that should have been ready are not ready, nor beginning to be ready. The great national fund of upward of £400,000 collected for the families of the soldiers and for the sick and wounded is being so twisted round with red tape that complaints are already pouring in to the newspapers about its uselessness and inefficiency."—On last Saturday the Duke of Connaught presented a flag, the gift of the Queen, to the hospital ship *Maine*. In making the presentation the Duke said the Queen gave the flag as a mark of her appreciation of the charity shown by the American women. Never before, he said, had a ship sailed with the combined flags—the Union Jack and the Stars and Stripes.

**The Plague.**—The laymen on the board of health of New York have receded from the ridiculous stand which they first took, and have consented to the landing of the coffee from Santos arriving recently at this port. A ship with coffee has recently arrived at New Orleans from Santos. There was no sickness on the vessel during the voyage, and it is probable that the coffee will be landed after having been aired for two weeks. Mobile has given warning that no ships from a plague-infected port will be permitted to enter the bay, but will be sent to the national quarantine station either at Ship Island or the Dry Tortugas. The captain of the *Willowdene*, which brought the coffee to New Orleans, reports that on November 10th, when he left Santos, there were sixteen persons ill with the plague in the hospital. The Brazilian minister at Washington has received a despatch from his government announcing that the plague has visibly diminished in Santos since the middle of November. Only two cases were reported during the first two weeks of December. It is stated in the *Brazil Medico* that the

plague reached Santos about the middle of July, the first signs of its presence being an extraordinary mortality among the rats in one of the storehouses on the docks. Another epidemic among the rats was noted in the latter part of September, and the first case of the disease in man was discovered soon afterward in a house in the immediate vicinity of the storehouses. On October 18th, the existence of the plague in Santos was officially announced. In Mauritius during the first two weeks of December there were twenty-three new cases of plague and sixteen deaths. The total number of deaths from the disease thus far has been twenty-one. The American minister to China reports that the disease in Niu Chwang is diminishing, and it is hoped that it will soon be extinct, and that all danger of a recrudescence in the spring will be averted. The Japanese health authorities stamped out the threatened epidemic at Kobe very promptly and effectually, and the disease did not spread beyond the seven patients whose illness first revealed the presence of the plague in that city. The Peninsular and Oriental Line steamship *Ballarat*, from Calcutta, November 15th, for London, arrived at Plymouth on December 16th, with a native Indian fireman on board suffering with the plague. In Formosa during the past twelve months there have been 2,383 cases of the disease with 1,906 deaths, a mortality of nearly eighty-six per cent.

**The Society of Medical Jurisprudence.**—At the annual meeting of this society last week, the following were elected as officers of the society for the ensuing year: *President*, Frank Ferguson, M.D.; *Vice-President*, Theodore Sutro; *Treasurer*, D. McLean Shaw; *Recording Secretary*, John C. West; *Corresponding Secretary*, Alfred E. Ommen.

**The Czar's Physicians.**—A French journal states that there are no fewer than twenty-five medical men attached to the Russian court. There is first a physician-in-chief, and then come the physicians-in-ordinary and the honorary physicians. The surgeons-in-ordinary number three, and there are four honorary surgeons. Of ophthalmologists there are two, and other specialists abound in proportion. The Czarina has a physician, a surgeon, and three specialists. In addition to this goodly array there are a chiropodist-in-ordinary and an honorary chiropodist. The cynical may find here a satisfactory explanation of the alleged wretched health of this poor man.

**Proposed Filtration of the New York Water Supply.**—Sanitary Superintendent Roberts has recently made a report to the board of health concerning the water supply of Manhattan Borough. He says that it is free from all sewage contamination, and repeated and careful examinations have failed to detect the presence of any pathogenic micro-organisms. The water is, however, often offensive in appearance, owing to the fact that all of the water in Croton Lake comes from surface drainage over a peaty soil, and storms bring down a mass of soil and vegetable matter which gets into the aqueduct in the freshet season. As a remedy for this, and also as a protection against possible contamination of the supply with pathogenic material, Dr. Roberts recommends the establishment of a system of filtration. The experience of Hamburg, Berlin, and other cities may be cited in justification of the enormous cost of such an undertaking.

**New York Polyclinic.**—Dr. M. Manges has been appointed professor of general medicine at the New York Polyclinic.

**A Hospital for Somerville.**—A number of the citizens of Somerville, N. J., have been actively employed for several months in raising funds for a hospital in that place, and it is now announced that enough money has been subscribed to insure the erection of a building. It is said that ground for the hospital will soon be broken.

**Early Recruits for the International Congress.**—The Chicago *Tribune* announces that more than four hundred doctors from Illinois, Iowa, and Missouri are arranging to sail from New York on the steamship *City of Rome* on June 30, 1900, their main object being to attend the meetings of the Thirteenth International Medical Congress at Paris in August.

**A Congress of Scientific Societies.**—The American Association for the Advancement of Science and nine allied societies will meet in annual session at New Haven on December 28th and 29th. The other societies are the American Society of Naturalists, the Association of American Anatomists, the American Morphological Society, the American Physiological Society, the American Psychological Society, the American Folk-Lore Society, the Society for Plant Morphology and Physiology, the American Chemical Society, and the Archæological Institute of America. The discussions of the American Morphological Society will take place in the Peabody Museum. The American Anatomists will meet at the Yale Medical School. The Physiological Society will meet in the Yale Biological Laboratory. The Psychological Society will meet in the Yale Psychological Laboratory. During one of the sessions of the American Society of Naturalists there will be a general discussion on "The Position that Universities Ought to Take in Regard to Investigation." In this discussion Professor Dwight of the Harvard Medical School, Prof. Russell H. Chittenden of Yale, Prof. William B. Scott of Princeton, and Prof. Joseph Jastrow of the University of Wisconsin will speak. Professor Goodwin of Harvard will deliver an address before the Archæological Institute on "The Hero Physician."

**Women Dentists.**—The editor of the *Medical Press*, commenting upon the suggestion of a woman's paper that dentistry would prove to be a lucrative profession for women, the opinion being based upon the fact that there is at the present time a woman who is successfully practising as a dentist in London, says that he would not have thought that dentistry would have commended itself much to woman as a professional occupation. Regarding the fact that there is one woman dentist in London, he says that "of course the old argument will not fail to operate here, that 'one

swallow does not make a summer,' and whether women would or would not prove to be good dentists could be determined only by actual experience. Meanwhile, there would probably be few who would care to make the experiment." Our contemporary might study the subject to advantage here, for there are more than a dozen women dentists in the borough of Manhattan.

**Dr. Edmund L. Cocks** has been appointed by the commissioner of public charities visiting dermatologist to the Randall's Island Hospital.

**The Mutual Aid Association of the Philadelphia County Medical Society** is named as legatee of one-half the residual estate of the late Dr. Albert Fricke. The whole is estimated at $32,500.

**Decreasing Population of France.**—According to the vital statistics for 1898, just published, there were 843,933 births registered in France during that year, a decrease of 15,174. The deaths for the same period numbered 810,073, an increase of 59,054 as compared with 1897.

**Practitioners' Society of Dallas, Texas.**—On December 1st the above-named society was organized at the Hermitage Hospital, and the following officers were elected: *President*, Dr. Lawrence Ashton; *Vice-President*, Dr. J. B. Titterington; *Secretary*, Dr. C. L. Johnson.

**Presbyterian Hospital, Philadelphia.**—At the formal opening of the Thomas Hoge ward of the Presbyterian Hospital, Dr. S. Weir Mitchell delivered an address, in the course of which he said: "All hospitals should be so managed that no man or woman should be allowed to come in and accept what the hospital can give without being questioned as to their being able to give something toward what they are to get."

**An Aged Practitioner.**—Dr. Charles F. H. Willgohs, of Doylestown, Ohio, celebrated his ninety-sixth birthday recently, and is still hale and hearty and thinks he has good reason to hope for the completion of a century. Most of the male members of his family have lived to the age of ninety or one hundred years, and his grandfather lived until he was one hundred and six. He was born in Kiel on November 20, 1803.

**The Irresponsibility of Prescribing Druggists.**—Justice McLean, in the supreme court, recently dismissed the complaint in a suit brought by a butcher against a firm of druggists on Eighth Avenue, to recover $10,000 damages, because one of the firm's clerks treated his injured finger and made it worse. Justice McLean held that druggists and drug clerks have no license to practise medicine and surgery, and that the complainant sought advice from the clerk in this case at his own risk.

**Widener Industrial Home for Crippled Children.**—Mr. P. A. B. Widener, the railway magnate and capitalist, has announced the purchase of a tract of land of thirty-six acres in the outskirts of Philadelphia, upon which he contemplates erecting and endowing a home, hospital, and school for crippled children at an estimated total cost of $2,000,000. The object of the institution will be not only to give proper medical and surgical attention to its charges, but also to furnish elementary and grammar-school training, and technical training for those more advanced in years, to qualify the patients, when discharged, to earn their own living. Special attention will be given to instruction in those trades that are adapted to the feeble-minded, as chronic cases will also be cared for. There will be twelve buildings in all, erected in Colonial style, of red brick and white marble.

**Navy Department,** Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending December 16, 1899. December 8th.—Assistant Surgeon W. L. Bell detached from the *Philadelphia* and ordered to the *Independence*. December 13th.—Assistant Surgeon W. M. Garton, order of December 6th modified, detached from the Washington navy yard and ordered to the *New York* immediately.

**Obituary Notes.**—Dr. Samuel Ketch, of this city, died very suddenly on December 14th, of disease of the heart. He was born in New York, in 1851, and was graduated from the Bellevue Hospital Medical College in the class of 1875. Dr. Ketch was an orthopedic surgeon of repute. He was for many years one of the surgeons to the New York Orthopedic Dispensary, and was also orthopedic surgeon to the Montefiore Home. He was a prominent member of the American Orthopedic Association, of which he was once the president.

Immediately after the stated meeting of the Orthopedic Section of the New York Academy of Medicine, held on December 15, 1899, had been called to order, it was on motion adjourned out of respect to the memory of Dr. Samuel Ketch, and a committee was appointed by the chair to express the sentiments of the section. The committee reported as follows: "The Orthopedic Section of the New York Academy of Medicine desires to express its profound grief at the sudden death of Dr. Samuel Ketch, one of its most useful and honored members. An original member of the Orthopedic Society, since merged in the Orthopedic Section of the Academy, he served as its secretary in 1889, and as its chairman in 1891, presented several valuable original contributions, and was at all times prominent in everything pertaining to its best interests and progress. Identified with the practice of orthopedic surgery for nearly twenty-five years, and in every way devoted to the advancement of his chosen work, his life was one of consistent uprightness, and honest and successful efforts."

(Signed) Henry Ling Taylor, Newton M. Shaffer, Reginald H. Sayre, *Committee.*

Dr. Emil Fischer, of Philadelphia, died in that city on December 13th, of chronic gastritis. He was born in Germany, but came to this country with his parents in early life, and was graduated from the Jefferson Medical College in the class of 1855. He was one of the founders of the German Hospital in Philadelphia.

## THE PRACTITIONERS' SOCIETY OF NEW YORK.

*One Hundred and Fiftieth Regular Meeting, Held on Friday, November 10, 1899.*

A. Alexander Smith, M.D., President, in the Chair.

**History of a Case of Malarial Fever of Pernicious Type which Proved Fatal in Less than Forty-Eight Hours after Admission to Bellevue Hospital.**—Dr. A. Alexander Smith reported this case, as follows: S. J. P——, male, aged forty-four years, married, a native of the United States, was admitted to Bellevue Hospital on October 11, 1899, at 11:55 P.M. His occupation was that of a farmer, his habits were good, and his family history was negative. He had lived in the northern part of the United States until 1886, when he went south to rid himself of bronchitis, from which he had suffered. Since then he had lived in the southern part of the United States, chiefly in Florida and South Carolina, until three months before his admission to the hospital, when he came to New York. In 1895 he suffered from an attack of extreme nervousness and exhaustion which continued about three months. He lost flesh during this time, but was not compelled to go to bed. During his illness he vomited, and suffered severely from diarrhœa. He had no chills. In the summer of 1898 he suffered from an attack of malaria lasting ten weeks. He had a chill every evening, followed by high fever and thirst. His medication during this attack was crushed ice and calomel. After he ceased having chills he received a small quantity of quinine in small doses, about a drachm in all, as near as he could estimate. After this attack he gained strength and remained in fair health until his present illness. Five weeks before his admission he again began to suffer from chills. The paroxysms occurred every day and were followed by high fever, thirst, drowsiness, and headache. He had continuous headache and suffered much from pain in his back and the larger muscles of his body, especially the calves of the legs. One week before admission he became so weak that he was obliged to remain in bed. That night, after the chill, he became delirious, and complained more than usual of the headache and the pains in his muscles. He had been delirious every night since then, but in the morning, although his headache was severe, his mind was clear. During the three days previous to his admission to the hospital he suffered almost continuous nausea and vomited repeatedly, the vomiting occurring most frequently when his fever was high. During his illness his bowels had moved about once in two or three days, the discharges being of a dark fluid consistency and of very foul odor. Upon the patient's admission he was semi-comatose; he could be partially aroused by vigorous shaking, but could not speak intelligently. He was poorly nourished and very anæmic. His respirations were sighing in character, though deep and quite regular. The pulse was regular, but weak. The heart was normal in size; first sound weak but clear; there was a systolic murmur at the base. A few moist râles were heard over the posterior part of both lungs. The spleen was large on percussion, and was distinctly palpable, hard, and somewhat tender to the touch. Upon the morning following his admission the patient regained consciousness, could talk rationally, and gave the above history. At 8 P.M. he began another paroxysm. At ten o'clock his temperature was 104.2° F., pulse, 132. When he was admitted his temperature was 104° F.; his pulse, 110. Two hours later his temperature was 103.4° F.; his pulse, 114. At five o'clock the next morning his temperature was 98.5° F.; his pulse, 88. His temperature continued normal until the evening, when he began another paroxysm; with this, his temperature went up rapidly, and he soon became unconscious. Toward morning the temperature subsided and with it the alarming symptoms disappeared. At 9 A.M. of the third day his temperature was normal; his pulse, 100. At 6:30 P.M. on the third day, notwithstanding the administration of quinine hypodermatically, he began another paroxysm and was completely unconscious in half an hour. He died five hours after the beginning of this third paroxysm, at 11:30 P.M. Examination of the blood showed many intra- and extra-corpuscular plasmodia malariæ. Some were crescentic. There were much free pigment and many leucocytes of various sizes. Many of the leucocytes were pigmented. Thirteen plasmodia were found in a single field. At the autopsy the spleen was found to be greatly enlarged, weighing fifteen ounces; it was of a dark chocolate color, and soft and mushy in consistence. The gray matter of the brain was pinkish in color, and the ventricles were somewhat dilated. The pia over the lateral hemispheres was markedly œdematous and opaque; over the cerebellar lobes it was pinkish in color, and dotted with numerous petechial hemorrhages. Both kidneys showed the lesions of interstitial nephritis. An examination of the remaining organs of the body proved practically negative.

Dr. W. N. Berkeley, who had made a microscopical examination of sections of the various organs in the case reported by Dr. Smith, stated that sections of the liver showed that the cells of that organ were extensively degenerated and disorganized, the nuclei frequently failing to stain. There were also infected red cells, and large numbers of heavily pigmented leucocytes sticking to the walls of the capillaries. A smear from the spleen showed immense numbers of intra- and extra-cellular parasites; also numerous ovoids, crescents, and segmenting organisms, and large quantities of pigment; the last sometimes free, sometimes enclosed in the leucocytes. The spleen tissue itself showed a large increase in the supply of red cells, many of them infected. A large number of leucocytes of all kinds and of plasma-cells were also present, besides other extremely large cells (macrophagi) which had taken up red cells, lymphocytes, parasites, and pigment to such a degree that their nuclei, if present, were entirely concealed. Hyaline thrombosis was frequent. The general impression gained from an examination of the spleen was that it had been simply overwhelmed by the germ and its toxins. The meninges of the brain, particularly in the cerebellar region, were intensely injected, showing that a meningitis had been well under way. The pancreas was fairly normal in appearance, excepting that it contained localized foci of necrosis, in which the cellular nuclei were much disintegrated. All the organs, in fact, showed that they were overwhelmed by the intensity of the infection. In the bone marrow it was remarkable that but few segmenting parasites could be found in comparison with the immense numbers present in the spleen. In connection with his remarks, Dr. Berkeley showed a number of microscopical sections of the liver, spleen, pancreas, and brain, with smears from the spleen and bone marrow.

Dr. H. M. Biggs said that the wife of the patient whose history Dr. Smith had reported had also suffered from malarial fever, apparently of the same type as that of her husband. She had only a single paroxysm, however, with high temperature, but the evidences of toxæmia were much less marked than in her husband's

case. His resistance to the poison had probably been lessened by the long duration of his illness.

Dr. A. A. Smith said that the only paroxysm which the man's wife had, began while she was at the hospital, visiting her husband. It was noticed that her cheeks were flushed, and it was then ascertained that she had a high fever.

Dr. E. G. Janeway referred to several cases of malarial fever of the pernicious type which he had seen occur among Italian laborers at the time of the construction of the West Shore Railroad. He said this was largely due to their manner of living and surroundings, and it went to show that this type of malarial fever might occur, under certain circumstances, even in the vicinity of New York.

Dr. Smith, in reply to a question by Dr. Brannan as to what form of plasmodium had been found in the case under discussion, said that nearly every variety had been found, excepting the rosettes and the pigtails. The small round and crescent forms were found in great abundance, especially in the spleen and to a lesser degree in the liver. Large deposits of free pig ment were also found in these organs. The man died during a paroxysm, apparently from toxæmia. There were no cerebral symptoms, excepting delirium and intense headache. During his stay at the hospital, he had received only a single dose of quinine, which was given hypodermatically. Through a misunderstanding, quinine was not administered until just previous to the man's death. Fifteen grains of the drug were given, in combination with urea, with the idea of doubling or tripling it on the following day, but the man died too quickly. The dose given apparently produced no effect whatever. The combination of quinine with urea had been found less irritating when given by the needle than when the quinine was given alone.

Dr. Walter B. James said the case reported by Dr. Smith was a most interesting one, and showed to what an enormous extent this micro-organism could exist in the human body. The speaker said he had often marvelled, in studying a severe case of malaria, at finding the patient comparatively comfortable and his life not endangered, in spite of the presence of large numbers of these organisms in the blood. He said that he had seen quite a number of cases of pernicious malaria which resulted fatally. The sections exhibited by Dr. Berkeley, however, showed more of the organisms than he had ever seen before. It had always seemed to him that the difference between the pernicious and the non-pernicious type of malaria was simply one of degree. The organism in the former was apparently similar to that found in the milder cases, but the system was overwhelmed by the large number of the organisms.

Dr. Francis P. Kinnicutt said that in the autumn of 1898 many of the soldiers who returned from Cuba suffered from malarial fever of a severe type, and it was found necessary to give quinine in enormous doses; not infrequently from forty to sixty grains were given hypodermically in the course of twenty-four hours with excellent results. He said that he thought lives were saved at that time by giving the drug in such large doses. Some of those patients who were suffering from pernicious malarial fever were in a state of coma, and their condition was apparently hopeless, but after the injection of heroic doses of quinine they recovered. In reply to a question, Dr. Kinnicutt said there was very little local irritation after these injections.

**Demonstration of Preparations of Mosquitoes, Illustrating their Supposed Relation to Malaria.** - This paper was read by Dr. W. N. Berkeley (by invitation; see page 917).

Dr. Beverley Robinson said that at the recent meeting of the New York State Medical Association Professor Osler read a paper in which he referred to malarial fever as we see it in the North, and laid down the two following propositions in regard to its diagnosis: (1) That intermittent fever which resisted quinine was not of malarial origin: (2) In these localities a continued fever was not due to malarial infection. Dr. Robinson said that individually he begged to protest against the absolute manner in which these propositions were laid down, and their unqualified acceptance by the profession. The speaker said he had seen cases of undoubted malarial fever, in which the diagnosis was based upon both clinical observation and the use of the microscope, which resisted the action of quinine intelligently administered, and in which the aid of other drugs had to be invoked He had also seen cases of continuous fever which proved to be of malarial origin.

Dr. E. G. Janeway said that in former years, before we had the assistance of the microscope, except by disclosing free pigment or pigmented leucocytes, it was often very difficult to decide between malarial and other types of fever. The administration of quinine did not always afford us a prompt and certain method of diagnosticating or excluding malaria in these doubtful cases; this might be due to the preparation of quinine employed, or to its method of administration, or to some idiosyncrasy of the individual. The speaker said that in a case which came under his observation he had been obliged to give gr. x. of quinine every two hours for twenty-four hours in order to check an intermittent fever which had lasted for some time, and which had remained unaffected by quinine taken in the ordinary way. In the case he referred to, the fever recurred every day, and in order to check the attacks gr. cxx. of quinine were given in solution within twenty-four hours. When, in a case of malaria, we failed to get any effect from the quinine, the possibility of substitution or an inferior preparation of the drug should not be lost sight of. Dr. Janeway said he was inclined to the opinion that the Peruvian quinine, which was generally used in former years, but was now very scarce, was more potent than the East Indian drug, which was obtained from the second growth of the bark.

Dr. Kinnicutt said that, speaking largely from memory, he could not recall a single case of malarial fever, positively proven to be such by the discovery of the plasmodium in the blood, which failed to yield to quinine, providing the drug was given sufficiently early in the attack. He had seen patients die of malaria, but in those cases the quinine was given too late.

Dr. James inquired whether Dr. Kinnicutt included cases of chronic malarial poisoning, with the presence of a large number of crescents in the blood.

Dr. Kinnicutt said he had excluded chronic cases by his remark, "providing the drug was given sufficiently early in the attack." He referred only to acute cases, as they were seen in hospital or private practice. When the history extended back for a year or two the quinine often lost much of its potency.

Dr. James said he had seen cases of malaria of the pernicious type which were early and vigorously treated with quinine, given in as large doses as was deemed advisable, but in spite of this they terminated fatally. No complicating lesions were found. He recalled one such case at the New York Hospital; the diagnosis of malaria was undoubted, the blood being loaded with plasmodia, principally of the annular and æstivo-autumnal types. Quinine was immediately administered, both by mouth and hypodermatically, but in spite of this the man died. The autopsy disclosed no lesions other than those belonging to malaria. Dr. James said he was under the impression that in tropical countries malaria often failed to yield to quinine, because the poisoning was so intense.

Dr. J. W. Brannan said the cases of fatal malaria cited by Dr. James, in which the patients were in an almost moribund condition when they were brought to the hospital, or the type of malaria seen in tropical countries, could hardly be included in the class referred to by Dr. Osler in his recent paper on the subject. Dr. Osler referred to malarial fever as we see it in the North.

Dr. Robinson said he just happened to recall a case which illustrated one of the points under discussion. The patient was a young lady who lived in the neighborhood of Poughkeepsie; she had been suffering from malaria, and the local physician who treated her had dosed her with quinine continuously and to such an extent that Dr. James, who had seen her several times in consultation, forbade its further use. Subsequently her fever returned, and Dr. Robinson was asked to see her. A change of climate was ordered, and she went to the mountains, where she promptly recovered. The only medicine she received there was the compound tincture of cinchona.

Dr. James said he recalled the case to which Dr. Robinson referred. When he saw the patient, she was suffering from chronic cinchonism, not from malaria. He said it had been his experience in many cases that while it was easy to check the malarial paroxysms, it was often very difficult to rid the system permanently of the malarial poison.

Dr. Janeway said that, in former years, all cases of fever of doubtful or unknown origin were apt to be regarded as malarial. In true malaria, quinine, properly administered in sufficient doses, usually produced its effect. The speaker said that in obstinate cases he usually combined the quinine with opium and capsicum.

Dr. Kinnicutt said it was the experience of many that after severe malarial infection the attacks of chills and fever recurred for a certain number of months, and then gradually disappeared. A certain degree of immunity was no doubt conferred by a change of climate. Many of the patients who were brought from Cuba last year suffering from malaria, after a course of treatment at the hospital remained free from the chills and fever for a month or longer; then the paroxysms recurred and the patients were obliged to return for treatment. These recurrences usually became milder in character as time went on.

Dr. James inquired whether Dr. Kinnicutt would classify such cases as he had just referred to as cases of acute malaria which were not cured by quinine.

Dr. Kinnicutt said his assertion had been that he had never seen an attack of acute malaria which had failed to yield to quinine: he did not say that it always cured it.

Dr. Andrew H. Smith said that in former years we heard much about remittent fever, and those cases were generally regarded as malarial in origin; there were no distinct intermissions, but typical remissions. Of late, such cases had almost disappeared. Under the use of large doses of quinine, the type of fever first became intermittent, and finally was overcome entirely.

Dr. Smith referred to the relative ease with which certain patients became cinchonized, and raised the question whether there was not some relation between the dose required to produce cinchonism in a given subject and the power of the drug over the plasmodium in the same subject. He also suggested that there was probably a certain quantity of synthetical quinine on the market.

Dr. Janeway said that most of the cases which were formerly regarded as remittent fever were undoubtedly typhoid. In the South, the æstivo-autumnal organism produced an irregular type of fever which resembled typhoid, but we rarely saw it in this climate.

Dr. Andrew H. Smith said that during his service in the army he was stationed on Staten Island for some time, and there he frequently observed a type of continued fever which had periodical remissions and which yielded to quinine. This type of fever, which had been described in various text-books, did not follow the course of typhoid.

Dr. Kinnicutt thought it possible that the poison of malaria varied in intensity and produced different manifestations at different times. In certain parts of New England where malaria had never before been known, it had recently become quite common, not only along the river courses, but even in the interior. The State of Massachusetts was now engaged upon some investigations in order to learn the possible or probable cause of these outbreaks.

Dr. Andrew H. Smith said that the appearance and disappearance of malaria in certain sections were often due to the water connections of such districts. When the Erie Canal was built, a section of it, near Cohoes, was above the level of the surrounding country. As a result, there was a constant leakage on both sides of the canal, the water covering the surface of the ground for a considerable distance. Soon afterward there developed in this section a most virulent form of fever and ague, generally of the tertian type. In another section of the country where malaria had been previously unknown, the disease became very prevalent after a dam was swept away and a large mill-pond was exposed to the action of the sun.

Dr. H. M. Biggs said that probably some of the cases of intermittent and remittent fever which were in former years looked upon as malarial in character were neither malarial nor typhoid, but were examples of what we now regard as septicæmia. Cases of septic infection, with the intermittent or remittent type of temperature, were not made out in the older days. The speaker said he did not refer to cases of septicæmia connected with a history of surgical infection, but those in which the source of infection was obscure, as many cases of infectious endocarditis. He referred as an example to a case now under his observation in which an irregular temperature had been running for more than four weeks, which was certainly of septic origin.

Dr. Janeway said that cases of so-called remittent fever, as seen in this city, had almost invariably, in his experience, proved to be cases of typhoid. This was much the same twenty-five years ago. During the Civil War the so-called Chickahominy fever usually proved to be typhoid. The great mistake was that of calling many of these cases typho-malaria; this term should never have been allowed a place in medical nomenclature. Cases of remittent fever, as seen in New York, almost invariably proved to be either typhoid, or sepsis, or tuberculosis. He said he was recently called to see a young man who had come here from the South. He was said to have suffered from remittent fever while at home. His temperature had been irregular, running up to 104° F. He had recovered, but on coming to New York had had another attack with fever; the spleen was enlarged; no malarial organisms were found in the blood. He had come from a place in the South where one of our military camps had been located last winter. At the time he was sick in the South, his brother, who had arrived from the same place some days before his illness, was taken down with an attack of typhoid fever. The probability was, Dr. Janeway said, that both the brothers were suffering from typhoid, which had been proven by the eruption, Widal reaction, absence of plasmodia, and course of fever—evidently a relapse of typhoid.

Dr. Robinson asked if there was any such thing as a simple continuous fever, which disappeared in the

course of a week or ten days, and which was neither typhoid nor malaria. A case of this kind, apparently, had recently been under his observation. The patient was a young man who was suffering from a continuous fever, which was first regarded as suspicious of typhoid. No malarial organisms were found in the blood, and no evidences of leucocytosis. The fever gradually abated, and disappeared entirely within a week or ten days. French writers laid great stress upon "bluish spots (*taches bleuâtres*) from three to eight lines in diameter, not elevated and not disappearing on pressure" (Flint), to differentiate simple fever and typhoid fever. These spots appeared upon the abdomen and the upper portion of the thighs. They might occur occasionally in typhoid fever, and apparently were quite characteristic abroad in cases of simple fever (Valleix: "Guide du médecin praticien," vol. i., p. 8).

Dr. Janeway said a case like the one reported by Dr. Robinson might be accounted for on the basis of a grippe febricula, or a typhoid febricula. The latter was sometimes seen in connection with epidemics of true typhoid fever, and ran its course in from three to ten days.

## THE NEW YORK PATHOLOGICAL SOCIETY.

*Stated Meeting, November 8, 1899.*

T. Mitchell Prudden, M.D., President.

**A Case of Hemorrhagic Infarction of the Small Intestine.**—Dr. Leon T. Le Wald presented this specimen. At the autopsy a thrombus had been found in the superior mesenteric artery. It had evidently caused a hemorrhagic infarction and necrosis of the intestine, followed by perforation, general peritonitis, and death. The patient had been admitted to the hospital about twelve days before death, so that the infarction had evidently occurred while in the hospital. It had not been diagnosed during life. The man had been a heavy drinker. He had been well and working up to three months previous to coming to hospital. He had then begun to suffer from shortness of breath on exertion. For the past two months there had been increasing shortness of breath with attacks of orthopnœa and moderate whitish expectoration—never bloody. About three weeks before admission his feet had become swollen, and had remained so since that time. The urine had diminished in quantity. He was poorly nourished, and the skin presented a yellowish appearance. The chest was barrel-shaped, and the percussion note was of a wooden quality, the expiration being prolonged and of low pitch. The cardiac dulness was indistinct. No murmurs could be heard. The pulse was rapid, small, and of high tension, and there was considerable thickening of the arteries. The liver extended just below the free border of the ribs. The extremities were slightly œdematous. Two days later, or on February 25th, it had been noted that there were less dyspnœa and a better pulse. He had been treated for chronic nephritis. On February 26th he had expectorated some bloody fluid, and yet two days later he had been much better. Over the sternum a soft, blowing diastolic murmur was heard at this time, and the pulse was large, full, quick, and soft. On March 8th it was noted that the patient had been markedly worse for three days, and had complained of cramp-like pain in the epigastrium. Over the base of the right lung were heard numerous crepitant râles; over the left lung, increased dulness. A soft, blowing diastolic murmur continued to be heard over the sternum. The pulse was small and wiry. He was vomiting frequently. On admission his temperature had been 99.3° F. On March 5th, or at the time when he had complained of the epigastric pain, his temperature had been normal. Two days later it had risen to 103°. On March 9th he had died. At the autopsy, the lungs had been found congested, and at the base of the right lung was a large hemorrhagic infarction. The heart was enlarged and dilated. There was extensive atheroma of the aorta, with calcification. The kidneys were enlarged, each weighing eight ounces. The capsules were adherent, and their surfaces were granular. There was an infarction in the right kidney. The liver weighed only three pounds ten ounces. Its surface was smooth. On section it was of a pale yellowish color, and the lobules were indistinct. The spleen was small, weighing four ounces, and on section showed an increase in connective tissue. The intestines were matted together by fibrinous adhesions, and there was a large mass of intestinal coils in the umbilical region. On separating these adhesions a perforation had been found in a coil of the ileum, about three feet above the junction of the ileum with the cæcum. The intestine for a distance of five inches on either side of the perforation was dark and gangrenous, and on opening the bowel the mucous membrane in this region was found softened, and the walls were dark, and infiltrated with blood. The corresponding mesentery was in a similar condition. On opening the superior mesenteric artery a firm thrombus had been found in one of the branches of the artery corresponding to the blood supply of the necrosed part of the intestine. The speaker said that the fact that there were infarctions of the lung, kidney, and intestine would point to an embolic process followed by thrombosis. Fatal cases of this kind had not been very numerous. In one reported case in the *Glasgow Journal* the symptoms had been very similar—shortness of breath, dropsy of the extremities, and a few small hemorrhages from the lung, and severe colicky pains in the abdomen, with bloody vomiting a few days before death. This case had also presented a hemorrhagic infarction of the intestine, although there was no perforation. The clinical diagnosis was difficult, but the sharp pain in the abdomen and the absence of the usual signs of strangulation were significant.

Dr. E. Hodenpyl referred to a case of thrombosis of the superior mesenteric vein recently seen at autopsy, in which the symptoms had been quite different. The patient, a man aged thirty-five years, had been seized four days before death with rather severe colicky pain in the abdomen. There had been no disorder of the bowel. The man had not seemed to be very sick at first, but had come to the hospital in an ambulance from a long distance, and on reaching the hospital had been in collapse. The autopsy showed a total thrombosis of the superior mesenteric vein, including all of its branches. There was a little atheroma of the aorta, but no history of syphilis could be obtained. The mesentery itself had been œdematous. With the exception of a moderate amount of phlebitis of the vein there was no clew to the origin of the process. There had been no elevation of temperature.

**Report of a Chemical Examination of a Knife-Grinder's Lung.**—Dr. Eugene Hodenpyl said that the subject of this report was a knife-grinder, thirty-five years of age, who had died of pernicious anæmia. The history was that he had worked at his trade for fifteen years. For the first ten years, he was employed as a grinder and worked in a large room with some forty others; for the past five years he had worked in a very small and ill ventilated room at the same occupation with some seven others similarly employed. The lungs presented a maximum degree of pigmentation, and it had, therefore, occurred to the speaker that it might be instructive to determine the amount of carbon contained in the lungs, and, if possible, the amount of

emery and iron also. Such an investigation seemed especially desirable, since the speaker had been at the time studying the literature of "Staubinhalation" without finding a single case in which the amount of carbon had been determined in similar cases of anthracosis, and, moreover, upon inquiring among his colleagues, he had found that none had the slightest idea as to the amount of carbon which might reasonably be expected to be obtained from such a lung. There were many reports in literature, notably those by Arnold, in which gold and silver had been extracted from the lungs of artisans working with these metals, but no case had been observed in which the amount of carbon, emery, and iron had been determined in the lungs of knife-grinders. The technique employed was to digest the lung, which weighed 900 gm., and then obtain the charcoal, emery, and iron by precipitation. The lung was cut into small pieces, placed in a little water, to which was added two ounces of Johnson's preparation of papoid and enough hydrochloric acid to give a reaction of free acid in the solution. This mixture was kept at a temperature of 40° C. for ten days, when the lung became completely liquefied. It was then necessary, on account of the viscidity of the mass, to add large quantities of water, in order to secure precipitation. About sixty gallons of water were added, and this mixture was allowed to stand in a number of tall jars for many days until precipitation was complete. The precipitate was then repeatedly washed in water until it was believed that all of the substance soluble in water had been removed. It was then evaporated to dryness and powdered. At this juncture, Mr. Allan C. Eustis and Mr. A. N. Richards, assistants in the department of physiological chemistry of the College of Physicians and Surgeons, New York, kindly undertook the chemical examination, and the speaker took this opportunity of extending his thanks to these gentlemen for the very complete analysis which they had made.

Analysis of lung taken from the body of a knife-grinder:

Total weight of lung dried and powdered, 48.1009 gm. Total solids, 44.7986 gm.; water, 3.3023 gm.

Soluble in ether, 14.6017 gm.; insoluble in ether, 30.1969 gm.

Composition of the portion which was soluble in ether: Free fatty acids, 7.498 gm.; neutral fats, 4.044 gm., cholesterin, 3.037 gm. (lecithins?).

Composition of portion insoluble in ether: Proteids, melanins, etc. (total nitrogen × 6.25), 15.4759 gm.; charcoal (total carbon — proteid carbon), 7.1989 gm.; ash, 4.29095 gm.

Composition of ash: $K_2O$, 0.2167 gm.; $Na_2O$, 0.3523 gm.; CaO, 0.0965 gm.; $Fe_2O_3$, 0.0879 gm.; $Al_2O_3$, 1.4628 gm., $SO_3$, 0.0704 gm.; $P_2O_5$, 0.9565 gm.; $SiO_2$, 1.20434 gm.

Dr. Hodenpyl said that, on first receiving this report, he had been somewhat disappointed that the amount of carbon was not greater, but since then he had made some simple experiments which demonstrated that, after all, 7 gm. + of this particular charcoal was really an enormous amount to be obtained in a lung. It is to be remembered that this charcoal was in an exceedingly fine state of subdivision. Thus, on mixing 0.1 gm. of very finely powdered animal charcoal in 500 cc. of water, the fluid was only very slightly darkened. One-tenth of a gram of the precipitate from the lung, dissolved in 500 cc. of water, made the fluid almost jet black in color, even though of this 0.1 gm. represented only about $\frac{1}{4\frac{1}{0}}$ gm. of carbon. Again, it will be seen that about one-fourth part of the ash was in the form of an oxide of iron. The amount of emery was represented by oxide of aluminium and oxide of silicon. These two together made up about 2.5+ gm., so that considerably over one-half of the ash was in the form of emery, and the emery and iron together made up more than three-fourths of the total amount of the ash.

Dr. Prudden remarked that more than a barrel of water had been made as black as ink by the pigment contained in the lungs of this person. The investigation had an obvious and important bearing on infection through the lung, because it showed how many particles might pass all the safeguards which the air passages present.

**Three Cases of Duodenal Ulcer, Two with Symptoms of Acute Appendicitis.**—Dr. Harlow Brooks made this report.

Case I.—This was a female child, twelve years of age, in good general health up to a few days before death. She had been constipated at that time, and a calomel purge had been given. When it had operated she had begun to suffer from severe pain, and had died a few hours after. At the autopsy, on opening the abdomen the omentum was natural, but the transverse portion of the colon was distended with gas. In the right hypochondrium was a mass of adhesions, partly recent, involving the hepatic flexure of the colon, gall bladder, duodenum, and pyloric end of the stomach. The common bile duct was occluded by adhesions. The surrounding peritonitis was quite sharply localized. On the internal wall of the second portion of the duodenum was a mass of old adhesions, and opposite this the wall of the duodenum was sacculated and of a purple color. The duodenum contained 2 c.c. of normal chyme. An area of the mucous membrane, one and one-half inches in diameter, was the seat of an erosion. This ulcer was not punched out, and microscopically it gave no evidence of tuberculosis or of anything else indicative of its origin. No other lesion of the digestive tract was found. The parents had been healthy.

Case II.—This was a Russian, about thirty-eight years of age, who had entered Trinity Hospital with a supposed abscess of the lung. He had been operated on for this, and a large quantity of pus, devoid of odor, had been opened up. Two weeks later an abscess had formed in the groin, and had been incised. Later on there had been symptoms strongly indicative of appendicitis, and the abdomen had been opened. The abdominal cavity contained about one litre of thick, creamy odorless pus which bacteriologically contained streptococci. At the autopsy, all the operation wounds were in a healthy condition. There was a sacculated empyema in the pleural cavity, and connected with the pus pocket found in the abdominal cavity. There were many areas of old peritoneal adhesions. The spleen was almost bifurcated by an infarction. The main pus pocket had been bounded by the spleen, the posterior surface of the pancreas and duodenum, and the posterior abdominal wall. A well-defined abscess cavity occupied almost the entire head of the pancreas, and this had undoubtedly been the original focus. The mucous membrane of the duodenum showed a characteristic punched-out ulcer situated near the pyloric ring, the base had been healed over. A similar lesion was located in the wall of the stomach also near the pylorus, but this was completely perforated. There was no inflammatory action around the ulcers. The liver showed marked interstitial cirrhosis and several gummata of considerable size.

Case III.—In this case a man, twenty-nine years of age, had been admitted to the J. Hood Wright Memorial Hospital to the service of Dr. Le Boutillier. For the past three years the patient had had nausea and vomiting in the morning. For two months previous to admission he had been passing a large quantity of dark, irritating urine. He had been told several times that he had had syphilis. Just before coming to hospital he

had been on a long drunk. He then developed pain about the umbilicus and vomited clear fluid. On the day previous to entrance he had had a sudden chill. On inquiry it was learned that he had had a somewhat similar, but less severe attack some years ago. There were moderate distention of the abdomen, and tenderness with moderate rigidity of the left rectus muscle. The diagnosis of general peritonitis, probably originating from appendicitis, had been made by both his attending physician and the hospital staff, and accordingly the abdomen had been opened. About one litre of fluid containing shreds of fibrin had escaped. The vermiform appendix was swollen and congested. It was amputated, and the stump inverted. The patient died after about thirty hours. Though the external coat of the appendix was eroded, no perforation could be detected, and nothing to account for the peritonitis. At the autopsy, eight hours after death, both œsophagus and trachea showed many tiny healed ulcerative patches. There was general fibroid enlargement of the lymph nodes. The abdominal cavity contained 500 c.c. of slightly turbid fluid, and the entire peritoneum was covered with an even fibrous covering. There was absolutely no odor to the exudate. There had been natural reaction near the field of operation, and the wound and stump of the appendix appeared healthy. Near the cardiac extremity of the stomach were numerous areas of submucous hemorrhage. On the superior anterior surface of the duodenum near the pylorus was a conical perforation with apex extending out to the peritoneum. The ulcer was nearly 1 cm. deep. There were no evidences of acute inflammatory action about the perforation, and the appearance was that of a recent ulcer produced by mechanical means. Sections of the appendix when examined microscopically showed an inflammatory exudate on the outer surface, but in none had it extended through to the endothelium. There was extensive degeneration of the glandular tissue including the glands of Brunner, due to post-mortem digestion or possibly to early post-mortem change.

Ulcers of the duodenum, the speaker said, were very rare. Perry and Shaw, in 17,652 autopsies, had found only fifty cases of duodenal ulcer. It was more common in males. Excluding the cases following burns there were but eight women to forty men. This disproportion between the sexes had never been explained. The ulcers following burns were of a different type from the duodenal peptic ulcers present in these cases. These ulcers probably followed sharply localized nutritional disturbance in the wall of the gut. They occurred most frequently when there was hyperacidity of the gastric juice. This would seem to be confirmed by the fact that they were rarely found below the first portion of the duodenum. The predisposing causes were not yet known. Perry and Shaw had found twenty-five cases associated with tuberculosis. None of the authorities seemed to consider syphilis one of the causes, yet, in his opinion, this was a very probable cause. It should be noted that two of his subjects were syphilitic. The fact that the symptoms had simulated appendicitis was of clinical interest. It was well to remember that the pus associated with a peritonitis set up by the perforation of a duodenal ulcer was devoid of odor, in marked contrast with the usual condition found in cases of appendicitis. The aspiration of a few drops of pus prior to operation might give assistance in deciding on the true condition present.

Dr. Van Gieson introduced the subsequent speakers, Mr. Frank and Mr. Weil, on the subject of "Neuron Retraction," and remarked that this theory had been one of the guiding principles of the researches at the Pathological Institute of the New York State Hospitals for the past three years. In endeavoring to make clear what was meant by neuron retraction it would be necessary to recall briefly the relation between mind and body, between psychomotor manifestations and physiological and pathological processes in the nervous system. The relation between these two sets of phenomena was not, as is too frequently supposed, one of succession, but of coexistence. Dynamic processes in the nervous system were not transmutable into psychomotor manifestations. In each domain—in mind and its physical substratum—there were indeed uniformities of succession; but between these two the relation was not that of antecedent and consequent, but of parallelism. The terms neuron retraction and expansion should be applied to pathological processes in the neuron giving rise to catalysis and synthesis of neuron aggregates functionally associated. Concomitant with these physical processes of retraction and expansion of the neurons were psychopathic phenomena which might be termed dissociations and reassociations of consciousness. Correlative with catalysis of neuron aggregates occurring through retraction were the psychopathic waking states; concomitant with the reverse process of neuron expansion inducing synthesis of the neuron aggregates were the psychopathic sleeping states. The processes of retraction and expansion of the neuron were not universal for the whole nervous system. In the lower parts of the nervous system there was no such thing as neuron retraction and expansion; the neuron aggregates were firmly united, and in fact concrescent. It was rather singular to witness the division of investigators in psychiatry and neurology into two hostile camps, the one faction believing that retraction was universal for the whole nervous system, and the other, because some of its objectively minded disciples had demonstrated anatomically annectant neurons in an invertebrate or in some one place in the human nervous system, fell headlong into the belief that the whole nervous system was composed of concrescent neurons, and, what was still worse, that our mental life must be bound to the fixed and unassimilative type of pulses of consciousness. Neither of these views was right. The theory which recognized each of these views seemed to be the only tenable one. The speaker asked to be accorded the privilege of stating that the Institute where Mr. Weil and Mr. Frank had conducted their investigation was one of the first to recognize this theory, and had fully two years ago declared and insisted on the standpoint that the human nervous system was composed of both free, retractile neurons in the higher cortical spheres, and of concrescent neurons in the lower parts. The speaker desired to correct the apparent misunderstanding that the theory of neuron retraction in the above-mentioned institute postulated universal retractility for the whole nervous system. The scope of these introductory remarks hardly permitted of discussion of the process equivalent to retraction in the fixed and annectant neuron aggregates. There was, however, quite an analogous process. In annectant neurons this process could not be termed retraction, but was disaggregation. The breaches of continuity and their restitution had also parallel psychomotor manifestations which constituted respectively neuropathic waking and sleeping states, and were described in a paper entitled "Neuron Energy and Its Psychomotor Manifestations." The paper about to be presented was one of three correlated branches of investigation of neuron retraction pursued at the Institute, in which the subjectmatter was examined from both the inductive and deductive standpoints. In the paper of Mr. Weil and Mr. Frank, the psychomotor phenomena concomitant with neuron retraction were entirely discarded and the question was considered from a purely morphological and inductive point of view. In this paper the

morphological evidence of neuron retraction as furnished by the Golgi methods was shown to be wholly untrustworthy. In a second paper the argument used was to examine the cytological structure of the neuron, to study its analogy with the structure of other cells endowed with distinct motility, and also to consider in general terms some of the phenomena of psychomotor dissociations. In the third paper the argument was largely deductive. Neuron retraction and expansion were assumed. This was taken as a postulate and was verified by the study of abnormal psychomotor phenomena, especially the psychopathies. This last line of argument furnished the only cogent course of reasoning to prove the retraction theory. The theory could be substantiated only by the study of the phenomena of abnormal mental life by the deductive method, and those who attempted to investigate the question from an entirely inductive and morphological basis could hardly have a broad, intelligent conception of the nature of the problem. We had as yet no actual demonstration of neuron retraction, nor were we likely to have for some time to come. In fact, this was not absolutely essential for the establishment of the theory if neuron retraction was assumed, and if psychopathic phenomena and much in the course of the phylogenetic and ontogenetic evolution of consciousness were explained by this theory, and indeed verified the theory, it was perfectly justifiable to accept it. The great weight of proof of the retraction theory rested not on morphological and physiological basis, but on the study of the living phenomena of mental life. It was this line of study from the psychological and psychopathological standpoint that had led us to accept and rely on the retraction theory as a great and powerful guiding principle of our investigations. Those who opposed the retraction theory because it was not proven by tangible and actual objective demonstration might equally well be sceptical of the theory of molecules and atoms and the whole fundaments of physical sciences. No one had ever seen an atom or a molecule, or had been able to receive any perceptual recognition of them. These things were entirely conceptual and inventions of the imagination. But these conceptions of atoms and molecules were so universally verified by the phenomena of the physical world that no chemist or physicist hesitated to accept the atomic theory. Neuron retraction and expansion were far too subtle processes for objective demonstration, at the present time at any rate. We ought to bear in mind that the study of living phenomena was just as cogent and important in substantiating theories as laboratory work with lenses, test tubes, and crucibles. The speaker did not want to minimize the objective demonstration of pathophysiological processes in the laboratory. This had been and always would be of incalculable benefit, and rested our theories on a surer footing. But it was quite fitting with one of the greatest and most profound problems in mental and nervous life before us, to remember that the study of the living phenomena might give us a key and a grasp on the question when laboratory study of dead tissues would signally fail. Those who could combine both points of view had indeed the coign of vantage. The history of medicine showed that reflective clinicians again and again had in general terms foreshadowed theories of pathophysiological processes long in advance of their detailed elucidation in the laboratory, and he felt sure that the retraction theory would be established by the explanation of the living phenomena of consciousness in advance of the demonstration of the physical pathway beside which they travelled.

**The Inadequacy of the Evidence of Neuron Retraction as Furnished by Methods of the Golgi Type.**—The following paper, by Messrs. R. Frank and R. Weil, contained a brief statement of the results of work done by the authors during the past three years in the Pathological Institute of the New York State Hospitals in connection with the theory of retraction. All the histological evidence which had hitherto been advanced in support of the theory had been based upon the Golgi method; the object of the present research was an experimental investigation of the adequacy of that method as a criterion of histological changes in the nerve cell or its processes. The literature of the subject was extensive and would not be detailed in this place, a complete *résumé* being furnished by W. Ford Robertson in the last number of the English magazine *Brain*. In brief, neuron retractility was by the majority of observers regarded as a function of the protoplasmic processes, and was best manifested by the pyramid cells of the cerebrum and the Purkinjé cells of the cerebellum. Two changes were said to occur: First, the appearance of localized swellings, or "varicosities," along the course of the dendrites; and, second, the disappearance of the gemmules, or dendritic spines, at the site of these swellings. The two phenomena were supposed, except by Lugaro, to be correlated; the spinous processes were withdrawn into the body of the dendrite, and, by so doing, a localized swelling was produced. Human and experimental material of the greatest diversity had been investigated—of the former, brains of diphtheria, typhoid, insolation, etc.; of the latter, brains of animals poisoned by arsenic, lead, morphine, strychnine, chloroform, tuberculosis, hydrophobia, experimental strumipriva, experimental uræmia, and other agents. The method employed had always been the rapid Golgi (or Cajal) method, except in the case of certain recent works of Lugaro's, which had employed Cox's modification of the corrosive method. Criticism of the conclusions above stated had not been lacking. Both gemmules and varicosities were by some authorities considered to be artifacts. By others, *e.g.*, Lugaro, while their occasional authenticity was admitted, they were partly attributed to post-mortem processes; Lugaro asserted that the only form of the Golgi method which did not exaggerate the true number of varicosities was the Cox modification.

In this investigation, four forms of the Golgi method were made use of, namely, the rapid, mixed, and slow modification of the bichromate-silver method, and the Cox modification of the corrosive method. The number of animals used was forty-three. There were five cases of human material, three adults and two fœtuses; one dog, and thirty-seven rabbits. Of the rabbits, ten were normal; of the remainder, two were poisoned by morphine, one by strychnine, four by chloroform, and the rest by the injection of hypertoxic urine or serum. Nine of the rabbits were treated uniformly according to four methods, the three bichromate-silver modifications and the Cox; two were treated according to the rapid Golgi method and the Cox; the rest, according to the rapid, mixed, or slow procedure alone. In all, three hundred and forty-two pieces were sectioned. The cerebral cortex alone was studied. The conclusions reached were the following:

(1) The same material, when treated by different methods, yielded different results. The nature of the differences in case of each kind of material was as follows: All material treated according to the slow method of Golgi showed an almost absolute freedom from varicosities; these structures occasionally occurred, but with a relative frequency which was perhaps not greater than a fraction of one per cent. The mixed method and the rapid method might be considered together; these two methods yielded practically

similar results, as regards the varicosities and the gemmules. The gemmules were almost invariably present and generally regular, provided the dendrites had taken the impregnation. The varicosities occurred in variable proportions, although their frequency regularly was greater, and almost always very much greater, than was the case in the slow method; in some sections almost every dendrite was varicose, in others hardly any. In the Cox method, a fair amount of varicoseness was generally present at any stage of fixation. Gemmules were almost universally present and regular.

(2) The above results were independent of the nature of the material, whether normal or toxic. Normal material, as well as toxic, was regularly free from varicosities when treated by the slow method. Normal material, as well as toxic, exhibited a variable amount of varicosity, when treated by any of the other three methods used. It varied within exactly the same limits as the abnormal, that every degree of varicoseness could be illustrated with equal freedom from either, and, finally, that it was impossible for an unprejudiced observer to differentiate or distinguish between the two kinds of material.

(3) The same material did not yield constantly identical results, when treated by one and the same method. Pieces from the same animal, when immersed in the same fluids of the slow, mixed, rapid, or Cox method, might illustrate the extremes of varicoseness produced by that method.

The above conclusions seemed to demonstrate that the varicosities were to be regarded as artifacts of the Golgi method.

Drawings of many of the preparations were illustrated by the projection lantern.

The thanks of the authors were due to Dr. Van Gieson for his courtesy as director of the Pathological Institute.

Dr. Joseph Collins said that he had been specially gratified with the paper and its very convincing arguments. The fact that varicosities had appeared on other cells than the pyramidal cells had always been a great stumbling-block to those who had put forward facts from morphological experiments. He hoped to be able, at some time, to controvert most of the statements made by Dr. Van Gieson. He would not think of accepting his definition of the retraction theory.

Dr. E. D. Fisher said that it was interesting to learn from these experiments that these varicosities were the results of the methods employed, and had no special significance. He had always noted that Dr. Van Gieson took special pains to show the true nature of many of these phenomena, whereas other observers had seemed disposed to theorize on insufficient grounds. Perhaps the most convincing argument offered was the statement that the same appearances were presented by material from both normal and abnormal animals. He agreed with Dr. Van Gieson that a theory, no matter if it proved ultimately false, was of great advantage in studying a subject like psychology.

Dr. Prudden said that he had been deeply interested in the paper because it demonstrated the great value of careful technical procedure. He did not conclude, however, as another speaker had seemed to do, that this work should be regarded as evidence against the retraction theory, but rather that this sort of evidence was not good evidence, and that the retraction theory still remained, in so far as this study goes, neither proved nor disproved.

Mr. Weil said that by a number of methods it was impossible to demonstrate the presence of gemmules, but it was perfectly possible to demonstrate them by other methods. He was of the opinion that the majority of workers with the Golgi method were coming to regard the gemmules as a legitimate product. They appeared regularly and only on the cortical cells.

Dr. Van Gieson said, in response to Dr. Collins, that when different degrees of conduction in pathological conditions were plainly evident in one and the same set of neurons, it was difficult to give any simpler explanation, and one more in accordance with our knowledge of the physiology and morphology of the neuron, than retraction.

## Correspondence.

### OUR LONDON LETTER.

(From our Special Correspondent.)

MEETING OF GENERAL MEDICAL COUNCIL: BRUDENELL CARTER AND VICTOR HORSLEY; MIDWIVES AND THE OBSTETRICAL SOCIETY'S SHAM DIPLOMA; ONE-PORTAL SYSTEM — APPENDICITIS — SENILE SCROFULA — EXCISION OF CÆCUM — OBSTRUCTION OF VENA CAVA — DEATH OF MR. WHEELER.

London, December 1, 1899.

The General Medical Council met on Tuesday and is still sitting. The president opened the proceedings with an address connecting last session with this, and indicating the work to be done. With constant complaints about the cost of the sittings and the increase of their length, this part of the performance might well be omitted, as I have previously remarked. The agenda ought to suffice and the members set at once to business. There is no need for an address and none for moving or seconding a vote of thanks for one, at the expense of a guinea a minute. As much might, however, be said of several other parts of the proceedings, and then—why, we should hardly know our talkative Council.

As soon as business was begun there was a lively, not to say desperate encounter between Mr. Brudenell Carter and Mr. Victor Horsley. Both these gentlemen are hard hitters, and neither is troubled with undue respect for the other. They have met before, and personalities have given piquancy to their logomachies. On this occasion Mr. Carter had the best of it. He had to complain of Mr. Horsley's statements about the representation of the Society of Apothecaries in the Council, and he showed that they were altogether erroneous. He proved this completely. Mr. Horsley had said in his public speeches that Mr. Carter did not represent the society, but only twenty-four tradesmen who knew no more of medicine than of bootmaking. Such and other disparaging descriptions he applied to the twenty-four gentlemen who appoint Mr. Carter, speaking of them as the master and wardens. Mr. Carter told the Council he was elected by the court of the society, a body of twenty-four, of whom the master and wardens were three. Moreover, every member of that court was a member of the College of Surgeons and a licentiate of the society, and some of them were university graduates and fellows or members of royal colleges. No more proof was needed that Mr. Horsley had made a serious blunder, but Mr. Carter went on to pile up the agony by trying to show that his opponent knew the facts, producing a letter dated 1896, saying "these twenty-four persons, most of whom are on the Medical Register."

Mr. Horsley then spoke. He began by acknowledging that Mr. Carter had established that his description of the electors was not justified, and apologized for having misrepresented them. He then endeavored to justify some of his statements, arguing especially that Mr. Carter did not represent the society because

he was elected by the court only, a body of twenty-four. But he might as well have objected to the representative of the College of Surgeons, who is appointed by the Council of twenty-four also. How could such an argument affect the body he was addressing, which is largely composed of such "representatives"? Here was no justification of his statements about the society, and he would have done better to have made his apology for his strange mistake without comment.

After this incident was closed the subject of death certificates came up, and it was agreed to ask the president of the Local Government Board to receive a deputation on the urgent need of legislation on the matter. Applications for restoration to the register were then considered.

On Wednesday the midwives question was once more brought up. Mr. Brown proposed that the Obstetrical Society be informed that the Council can no longer assent to their holding examinations and granting pseudo-diplomas to midwives. You may suppose that this might meet with general support, seeing that the Council once condemned the society and threatened action. But no—the Council afterward climbed down and let their obstetric friends carry on their illegal traffic in sham diplomas on altering the form of the certificates with which they flood the country. This pusillanimity of the Council has been most disastrous, and the echo of it was heard in this debate when a direct representative of the general practitioners declared he could not be a party to calling the eminent obstetricians to account, and further would dissociate himself from any imputation that these eminent men carried on their examinations for the sake of fees. It has never been said that these men did so for personal pecuniary gain. But it has been proved that their sale of diplomas to midwives of three months' instruction is a very profitable traffic for their society. There is no legal right in this traffic, and if these eminent men persist in lawlessness, they ought to bear the penalty.

Mr. Brown's motion was, of course, snuffed out, the previous question acting as the snuffers. Another motion of his in favor of union of the colleges and the Apothecaries Society, so as to form a single qualifying board for England, fared rather better. It was carried by eleven to eight, but eight significantly abstained from voting, and three were absent. This may be said, that the Council has before tried to bring about an amalgamation, but the obstructions were the colleges.

Yesterday much of the time of the Council was devoted to its judicial functions.

Appendicitis was the subject at the Medical Society on Monday. It was introduced in a paper by Dr. Caley, who treated of its prognosis in the light of two hundred hospital cases. Of these ninety-nine were simple, *i.e.*, localized non-suppurative, and all terminated favorably. Thirty-one were localized with suppuration, and twenty-nine of these resulted in recovery. Twenty-three were complicated with general peritonitis, and twenty of these were fatal. Forty-two were relapsing chronic cases, and all ended in recovery, thirty-seven of them having had the appendix removed. In the remaining five cases there were special complications, and three patients died. These statistics show a heavy mortality when there is general peritonitis, a low mortality when there is a localized abscess properly treated, and quite a favorable course in mild cases, which constitute the majority of all cases of the disease. The special points for consideration in reference to prognosis were (1) local symptoms with special reference to pain and vomiting; (2) general symptoms; (3) local signs on physical examination; (4) progress of the case. As to (1), persistent severe pain suggested a severe lesion and sudden increase of pain indicated an unfavorable turn. Persistent, severe vomiting is also grave. As to (2), temperature by itself is fallacious, but in conjunction with pulse and other symptoms is significant. Rapid pulse and bad general condition were ominous. As to the other points, the local signs were of great importance, and the progress of an acute case during the first twenty-four hours was perhaps most important of all. Recurrence is to be anticipated in quite one-third of the cases, and generally occurs within a year of the first attack. If chronic appendicitis remained, another acute attack should be regarded as sure to occur.

Mr. Owen said suddenness of attack was grave, and the sooner such cases were in the surgeon's hands the better. McBurney's point he found quite misleading. Dr. F. Smith said the chief thing to determine was whether suppuration had occurred, as in its absence temporizing was safe. Mr. Carless, on the contrary, said surgeons ought to anticipate suppuration instead of waiting for it, as they could thereby prevent peritonitis and remove the appendix, which was often not practicable when an abscess had formed. Mr. Moullin would intervene in all cases in which improvement did not take place in the first thirty-six hours, as by that time either suppuration had occurred or adhesions had begun, which would be sure to bring on relapse. Mr. Berry said he had become converted to expectancy. He had treated thirty-three acute cases by free incision and washing. Of them twenty-six resulted fatally. Out of forty-one patients treated by a limited incision through adhesions, only two died. He protested against washing out the abdomen, as a fatal practice. He said the incision should be just above and perpendicular to Poupart's ligament, as in the majority of cases that through the linea semilunaris would fail to open the abscess.

The president said he had seen many recoveries under common-sense medical treatment, but always called in a surgeon for his opinion.

Dr. Caley in reply remarked that early operation seemed to have much in its favor, but one could not usually get the cases early enough. He asked, too, whether an operation at an injudicious moment might not convert a local into a general infection.

Joint tuberculosis in the aged would seem to be more common than generally supposed, judging from some remarks made at the Clinical Society on Friday. A case was related by Mr. Marsh in a lady, aged seventy-one years, who in June, 1894, complained of pain and swelling in the left ankle. By October suppuration had taken place, and the joint was opened and drained. But pus burrowed up the leg in the sheaths of the flexor tendons, and wasting of muscles and general weakness ensued. In March, 1895, amputation through the lower third was performed and the patient improved. A year later periostitis of the left ulna went on to suppuration, and a sinus was left for three months. Nine months later, the patient being then seventy-three years old, the right ankle became affected. A further amputation was done in March, 1897, and healed in five weeks. In June an abscess formed over the site of the ulnar periostitis; it was opened, and slowly healed. She remained well for eighteen months; then at seventy-five years of age her right knee became affected, for which amputation in the lower third of the thigh was done four months later. No further trouble has occurred. The condition in all three joints was the same. The disease began apparently in the synovial membrane and led to destruction of the ligaments and cartilages, the bones being ulcerated in some spots. Mr. Marsh thought the older the patient the more rapid was the destruction of the joint attacked with tuberculosis.

Sir D. Powell said that in lung cases in the aged the tendency of the disease is to remain local, so that prognosis is more favorable than in the young, a remark with which Dr. Kidd concurred.

Mr. R. Johnson said that in the joints the disease was more virulent in the old than in the young, and asked for an explanation of the difference in virulence of carcinoma and tubercle in the aged, the growth of the former being slow but tubercle spreading rapidly. He also asked why the old were not oftener affected if the virulence depended on defective resistance.

Dr. Richards took a more hopeful view, as he had often had good results in his poor-law infirmary, owing, perhaps, to improved diet and rest. Out of five hundred post-mortems in the last two years in his infirmary, seventeen patients were aged over seventy years and died of acute tuberculosis; sixteen were between sixty and seventy years. About 6.6 per cent. of bodies examined post mortem (about half the number of deaths) were tuberculous.

Mr. Barker described a case in which he had excised the cæcum for malignant disease. He thought the disease rare, as he did the fact that it had caused obstruction. Some of the surgeons present did not consider it very rare, and mentioned cases they had had. On opening the abdomen in the middle line Mr. Barker found the small intestine greatly distended and opened it, when five pints of fetid liquid were evacuated. He was then able to feel a hard mass in the ileocæcal valve obstructing the bowel. It seemed dangerous to remove it at once, and he anastomosed the ileum to the hepatic flexure of the colon by suture, and closed the wound. Six weeks and three days later he made an incision over the cæcum and excised it with some of the ascending colon and six inches of ileum above the valve. The growth was carcinoma of the valve with excrescences projecting into the cæcum. The patient was present, looked well, and had resumed his work as a plumber. In the discussion the plan of operating in two stages seemed generally approved, and the suturing was preferred to the button. Mr. Hutchinson, Jr., said that on looking up the statistics of resection for gangrenous hernia he found the recoveries with the button were seven per cent., but with careful, direct suture four per cent.

Dr. Chapman brought the patient he showed last session with obstruction of the inferior vena cava, probably due to the pressure of a gumma. Under specific treatment there has been improvement, but the condition of the external veins is unaltered.

Mr. W. I. Wheeler, who was president of the Dublin Royal College of Surgeons in 1883, died on Saturday of typhoid. He began his active career as a resident in the City of Dublin Hospital, then became demonstrator in the school of the College of Surgeons. Afterward he entered the army and served in the Abyssinian war. On his return he became surgeon to his old hospital, and established his position as a leading surgeon in Dublin. He had been also an examiner in the college, and was a graduate of Dublin University, B.A. and M.Ch.

## ANOMALOUS PUPILLARY REACTION.

To the Editor of the Medical Record

Sir: In the last number of the Record there is a short report of a case of anomalous pupillary reaction in meningitis, by Dr. Seitz. I wish that if the doctor has any further details of the case he would report them at length, as the symptom is rare and interesting. De Schweinitz and Randall permit this statement on page 151 of the "American Text-Book": "A good deal of doubt has been cast upon this type of pupil reaction." It is what has been termed paradoxical pupil reaction. Knies tells us that it is of rare occurrence and that an explanation of the phenomenon cannot now be given. F. W. Higgins, M.D.

Cortland, N. Y., December 6, 1899.

## IS STATIC ELECTRIFICATION A SPECIFIC FOR ORGANIC AND STRUCTURAL NERVOUS DISORDERS?

To the Editor of the Medical Record.

Sir: The method of static electrification, the so-called wave current of which Dr. Morton speaks in a recent issue of the Medical Record (December 9th), has of course been in common use by others than himself for many a year. It certainly has the advantage over methods equally if not more efficient in simplicity of technique and ease of administration, but few will, I think, agree with him in making it a panacea almost for some of the most serious diseases, organic and structural, to which flesh is heir. Would that it might accomplish all that is claimed for it, but I fear it will not, and in my judgment it is quite as unfortunate to claim too much as too little. Some one has said that "originality is a thing we constantly clamor for and as constantly quarrel with." Dr. Morton has certainly not been backward in claiming not only originality, but entire originality, in the discovery of the static induced current, and although I would not quarrel with the originality, some of us have often felt like quarrelling a bit with his claim of originality.

I have in my possession an old, old book by one named Mauduyt, published in Paris in 1783, more than a hundred years ago, in which is given both in descriptive and illustrative detail what is now called the static induced current. Dr. Morton may have resurrected the method and improved it, but it is difficult to see how he could in any sense be said to have originated it. If he has ever given the slightest credit or in any way referred to the original source, it has not been my fortune to see it. A. D. Rockwell, M.D.

December 12, 1899.

## DANGERS IN THE HABITUAL USE OF ALCOHOL.

To the Editor of the Medical Record.

Sir: I have read with much interest Professor Atwater's report of the experiments which he has conducted at Middletown, Conn., under the auspices of the committee of fifty for the investigation of the drink problem. It has long been well known that the hydrocarbons, the oils, fats, saccharine substances, starch, and alcohol are heat-producing, and sources of energy in the human body. The recent experiments by Professor Atwater simply demonstrate that the human body can oxidize—use as fuel, creating energy—two and one-half ounces of alcohol in a day. It is urged that the alcohol can be more rapidly converted into energy than the hydrocarbons mentioned, ordinarily used as food, and may subserve a purpose in an emergency where rapid evolution of force is imperative. Unlike any other hydrocarbon used as food or as a beverage, alcohol has a peculiarly subtle effect upon the nervous system, forming a habit which becomes maniacal and uncontrollable in character before the habitué is at all aware of it. I am assured from observation extending through fifty years of professional life, that two and one-half ounces of alcohol or the equivalent in the finest brandies, whiskeys, wines, or ales, used daily for a period of time at all extended, will not fail to make an alcohol habitué of the most finely endowed man or woman in the world. The nervous system surely registers the abnormal impression no matter how carefully the two and a half ounces of alcohol may be taken. Once an habitué and under the control of the alcohol mania, the strongest man or woman becomes impotent to escape from the tyranny of its power.

In a neighboring town three years ago, fifteen pa-

tients were reported cured of the alcohol habit by the Keeley method of treatment: only two of these patients are sane to-day. Thirty-six years ago two of the noblest physicians, men of fine native and physical powers, commenced the use of two tablespoonfuls of the purest whiskey, to induce sleep when overworked. They were younger than myself. One gradually lost his standing and practice and died four years ago, filling a drunkard's grave; the other, possessing great native hardiness of constitution, lingers yet, a hopeless and helpless alcohol habitué, whom neither the Keeley cure, the entire medical pharmacopœia, nor the strongest moral aid has availed to save. It is far more difficult to treat traumatic injuries, fevers, influenza, pneumonia, and prevailing endemic diseases when the patient is a very moderate drinker, than to cure a total abstainer of equal vitality. I have been able to relieve permanently a number of persons, some of whom were women, who in the earlier stages of moderate drinking were struggling against the alcohol habit, unwittingly formed, and there is no work I regard with greater satisfaction.

I have always felt it imperative to enjoin upon these patients the necessity of total abstinence for life, as their only security, except in the direst medical extremity. Persons with a refined, sensitive, or diseased brain using habitually even the smallest amount of alcohol are in great danger. The most active and susceptible qualities of mental activity readily take on an unnatural excitation.

Two and one-half ounces of alcohol should never be used by any individual daily, except as a very temporary necessary expedient in an emergency or serious illness. It should then be conscientiously withdrawn by the attending physician, at the earliest moment when the necessity for its use has passed. Facts everywhere demonstrate that untold mischief results from the daily use of what is usually regarded as a small amount of the purest alcoholic liquors. I find many persons using no more and even less than two and one-half ounces of alcohol per day, or its equivalent, who are unconsciously habitués. The eyes and the skin of the cheeks, nose, ears, and neck show heightened coloring. This is far from being an indication of health. The use of an ordinary hand lens reveals a decided enlargement of the capillaries in these localities. If this vascular distention has taken place in the denser and less important structure of the skin, why must it not have occurred, even to a greater degree, in the far more numerous and more delicate capillaries of the cerebral tissues? The permanently heightened color indicates an advanced stage of the alcohol disease. The deceived victims, however, regard themselves as very temperate users of alcoholic stimulants, and no amount of argument can convince them that they are in any danger of becoming habitués. In such cases the observant practitioner cannot fail to discern evidences of serious organic changes in the cerebral, hepatic, and other tissues. The exhaustion that follows the burning out of the active fire kindled with a small amount of alcoholic stimulant is evidently in excess of the stimulation of the energies, as the nervous system after a little time imperatively requires increased stimulation.

Two and one-half ounces of absolute alcohol are equal in volume to five tablespoonfuls. This amount of alcohol is found in ten tablespoonfuls of the purest whiskey or brandy. I have recently secured the services of two eminent chemists who have analyzed six varieties of the finest wines, native and imported. I give the result of these analyses by volume in common measurements, each being somewhat less than the measure stated, to avoid fractional reckoning. Two of our finest California wines contain six tablespoonfuls of alcohol in a pint. One much-vaunted American wine has a little over eight tablespoonfuls of pure alcohol in one pint. One brand of port contains seven tablespoonfuls of alcohol to a pint. One French wine, imported and much advertised, contains five tablespoonfuls of alcohol to a pint. The lightest wine, a California brand, contains four tablespoonfuls of alcohol to a pint.

During a long and laborious professional life I have never taken of alcohol and its derivatives what would amount to a single pint of absolute alcohol. I have prescribed just as little of it as I could, and have never administered it to any of my children, even in severe illness, and they are now of adult age.

Alcohol and its derivatives are too thoughtlessly used and too carelessly prescribed by our profession, and any physician who has permitted his patients to become habitués through his counsel or neglect has not been a true friend to the unfortunate sufferers. Far better and more sure than the cure of the unfortunate is the preventive work which every physician, by every obligation to his fellow-men, is conscientiously bound to do.

I am positive that with our profession, more than with any other class of persons, lies the possibility of preventing the alcohol disease. By virtue of their sacred office physicians are, or ever should be, the protectors of the individual and the home, and the guardians of the public welfare.

C. A. Greene, M.D.

Castile, N. Y.

## SOME PRACTICAL OBSERVATIONS UPON THE PREVENTION OF APPENDICITIS.

To the Editor of the Medical Record.

Sir: The elaborate and exhaustive review of the history and literature of appendicitis, by Dr. Edebohls in the Medical Record of November 25, 1899, must be read with the close attention it so richly deserves. The appendix vermiformis is of such insignificant size that its existence was overlooked by anatomists until the sixteenth century. Physiologists have taken no notice of it yet. We are not told, and we do not know, what its functions are. They are remotely hinted at, as probably furnishing a lubricant for the fæces, but this has not been demonstrably proven. Not even Dr. Edebohls refers to them in his essay. But appendicitis, inflammation, or some other pathological condition of this mite of the intestinal canal is daily and universally heard of, seen, and treated by many, with unparalleled fatal results. There are other organs the physiology of which is unknown, such as the ductless thyroid and thymus glands, but the baneful results of their absence or removal are soon manifest.

But the removal of the healthy appendix vermiformis is easy and absolutely harmless; which leaves the question unanswered: "What is the vermiform appendix good for?"

It is authoritatively stated that fifty thousand deaths occur annually in the United States of America from appendicitis, whether under surgical or medical treatment is not known. This naked fact is appalling, and sufficient to stamp it as the most dangerous disease known, outranking variola, spinal meningitis, and perhaps pulmonary tuberculosis.

And yet appendicitis can be prevented by the removal of the appendix from healthy children. Why not perform appendicectomy on all children before school age? The technique of the operation is very easy in a healthy body, or one in which there is no pathological complication. Union by first intention is always attained under aseptic precaution. It is not more cruel or barbarous than compulsory vaccination,

or serum treatment, now so much in vogue. It is a prophylactic of absolutely certain results. It is true that such an act cannot probably be legally enforced, yet intelligent parents would rather choose this alternative than risk the dreadful ordeal of an appendicitis, especially when they have already had a sad experience of it in their own family. The removal of a healthy, not absolutely vital organ is largely practised on animals of the lower order with excellent results. The human body can always endure surgical operations better. With the judicious use of anæsthetics, the shock of such a simple surgical operation would be the least worthy of consideration, and a positive immunity from this dread disease would be assured.

The proposition will not meet with early or general acceptance, but it will be favorably thought of when no better remedy is found to improve the record of treatment of appendicitis.

It may not be improper to mention that some zoölogists and ethnologists believe that if appendicectomy is performed on all children for five or six generations, it is more than likely that the children of succeeding generations will be born without a vermiform appendix.

S. Pollak, M.D.

St Louis, Mo.

## THE WAR IN SOUTH AFRICA.

(From our Special Correspondent.)

THE RAPID HEALING OF MAUSER RIFLE WOUNDS—THE CARE OF THE WOUNDED—THE HOSPITAL DEPARTMENT OF THE BRITISH ARMY.

Durban, Natal, S. A., November 10, 1899.

We in Natal are now in the midst of war, and from a surgical standpoint no doubt your readers would be glad to hear of some matters connected with the all-absorbing topic.

I am sorry to say that by being accidentally shot through the thigh by one of my own men at revolver practice, I have been unable to proceed to the front, where I could have gleaned many interesting particulars. I am at present, however, partially recovered, and am acting as assistant surgeon at a convalescent hospital in the Legislative Building, Maritzburg.

Here most of our wounds are comparatively slight and nearly all are healed; most of these were received about fourteen days ago, and it is striking how quickly and cleanly they have healed. Those through the arm, leg, and foot, when not severing main arteries, are quite healed, and beyond a little stiffness the men complain of nothing. All the wounds so far seen by me have been inflicted by the Mauser bullet.

The British contingent from India brought with them a fully equipped field hospital with well-trained Indians as bearers and hospital assistants. The bearers are said to have shown great coolness and courage in going out under fire to carry in wounded.

The plan adopted by the medical department is that all wounded are sent from the front as soon as possible to Maritzburg, where several large public buildings have been made into hospitals. From here they are being dispatched in batches of a hundred or so to Durban, and thence straight away by ship, specially fitted, to Cape Town, where large convalescent hospitals are ready to receive them, the climate down there being dryer and healthier at this season than the subtropical climate of Durban during the rainy season.

The battle of Elandslaagte was a most unfortunate one for the wounded. The firing ceased only at dark, so that many of the wounded lay out all night in a cold rain, owing to the inability of the ambulance men to reach them Doubtless many died who might have been saved had aid reached them earlier.

## Medical Items.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 16, 1899:

| | Cases | Deaths. |
|---|---|---|
| Tuberculosis | 171 | 154 |
| Typhoid fever | 91 | 9 |
| Scarlet fever | 167 | 11 |
| Measles | 482 | 13 |
| Diphtheria | 273 | 37 |
| Laryngeal diphtheria (croup) | 9 | 3 |
| Cerebro-spinal meningitis | 0 | 4 |
| Chicken-pox | 29 | 0 |
| Smallpox | 2 | 0 |

**Combination among Medical Men.**—Combination seems to be the order of the day; all trades combine, both employers and employed alike, but there are many who lift their hands in holy horror at the idea of a medical practitioners' combination. No, he has been the knockabout so long that any alteration in the present state is viewed with surprise and alarm. Combination in the profession does not necessarily mean a combative organization, but rather it has its object to bring about a clearer understanding between themselves and their patients. We may take it for granted that the more contented and better paid medical men are, the better will it be for those under their care.—Excerpt from an address of Dr. Luther Cooke on "Medical Politics."

**An Ancient Roman Hospital.**—Herr Reber gives an interesting description of the recently discovered ruins of a Roman military hospital (?) at Beeden in Aargau. The building had a base area of forty-five by forty metres, and was adorned with a pillared portico of which the foundations still remain. The main hall had an area of one hundred and twelve square metres and was apparently divided by thin walls into separate compartments, each for a single patient. There were fourteen ground-floor rooms, of which the largest measured twenty-seven metres by three. Scattered through these rooms was a large number of medical and surgical instruments and apparatus of various kinds, including one hundred and twenty probes of all shapes and sizes, cautery irons, ointment pots and spatulæ (one of the former containing an ointment of white lead and lard), a bronze catheter, hand scales, knives, needles, and numerous vessels, some with artistic ornamentation. One room seems to have been used as a dispensary, for not only were scales and instruments for rubbing up powders discovered, but also two metal labels inscribed Manna I and Manna S, apparently denoting whole and half (semis) powders of frankincense, then often used as a hæmostatic. The only reasons for calling the pace a military hospital seem to be the facts that a stationary camp long existed in the neighborhood, and that we have no definite knowledge of Roman hospitals other than those for soldiers and slaves. Herr Reber considers that the absence of any arms or military accoutrements and the presence of numerous brooches or fibulæ of delicate workmanship, such as would be worn by women, are opposed to this theory.—Janus, in *Medical Magazine*.

**Rag-Sorter's Disease.**—This is an affection observed among workers in paper factories and presenting symptoms which closely resemble internal anthrax. It is presumably a bacillary disease, and the bacillus proteus hominis capsulatus has been found in the internal organs.—"Handy Book of Medical Progress."

**Sanitary Matters in Japan.**—The *Allgemeine Wiener medizinische Zeitung* states that in Japan the bureau of public health is connected with the internal department. The country is divided into seven sanitary districts, and each community has a sanitary council consisting of police officers and two local members of the profession, druggists or veterinarians, who confer with the local officials in all matters affecting the public physical welfare.—*Sanitary Record.*

**Mismanagement during the Crimean War.**—Mr. Justin McCarthy, in his "History of Our Own Times," refers in these words to the situation in the Crimea brought about by the blunders of the commissariat department of the British government at that time: "The winter (1854–55) was gloomy at home as well as abroad. The news constantly arriving from the Crimea told only of devastation caused by foes far more formidable than the Russians—sickness, bad weather, bad management. . . . On shore the sufferings of the army were unspeakable. The tents were torn from pegs and torn away. . . . The hospitals for the sick and wounded at Scutari were in a wretchedly disorganized condition. . . . In some instances medical stores were left to decay at Varna, or were found lying useless in the holds of the vessels in Balaklava Bay, which were needed for the wounded at Scutari. . . . Great consignments of boots arrived, and were found to be all for the left foot. Mules for the conveyance of stores were contracted for and delivered, but delivered so that they came into the hands of the Russians and not of us. Shameful frauds were perpetrated in the instance of some of the contracts for preserved meat. 'One man's preserved meat,' exclaimed Punch with bitter humor, 'is another man's poison.'"

**Winter Clothing.**—With the coming of December every one thinks of winter clothing, and as a clothing we all believe in wool. Undoubtedly, as the saying goes, "there is nothing to beat it." A man clothed in wool is far nearer to the condition of the natural monkey with whom he is said to have such affinities than when dressed in any other garb, even than when got up in furs or in the homely sheepskin. The trouble is that wool is difficult to wash, and very difficult indeed to sterilize without deterioration, whereas cotton and linen can be made not only to look clean, but to be really clean by the simple process of putting it in a copper and boiling it. If one inquires how woollen underclothing is dealt with by the ordinary laundress, one finds that it is washed in warm water well lathered with soap, and rapidly dried, preferably upon some form of stretcher, the aim being not entirely cleanliness, but the avoidance of the shrinking which is apt to take place if it be left long in water, and of the "going hard" which occurs if the fabric is boiled. The process is definitely laborious, and one that the poor find too tedious and expensive to be indulged in more frequently than is absolutely necessary. Hence, no doubt, what a contemporary calls the "dreadful smell of humanity" which characterizes a British crowd, for Great Britain of all countries in the world is the one whose inhabitants most affect woollen cloth. —*Hospital.*

**Word Deafness.**—Cases of word deafness being so exceedingly rare, no case is yet known in which recovery has taken place, and it would in all probability be difficult to bring it about. Owing to the patient's ability to speak, to read, and to write, by means in the main of the nervous mechanisms contained in the left hemisphere, this side of the brain would still continue very fully to perform its functions. Moreover, the situation of the lesion might be such as to prevent functional relations becoming established between the left visual and the right auditory word centres, and this being so the right auditory word centre would remain in an isolated condition. If, as in such a case, this centre should be thus cut off from all functional relations either with its fellow or with the visual word centre of the left hemisphere, it seems evident that comprehension of speech could never be restored—that is, no process of functional compensation would be possible.—BASTIAN: "Aphasia and Other Defects of Speech."

**The Plague and Mice.**—Dr. Donga, provincial medical officer of health at Venice, says: "An evident and well-demonstrated connection exists between the plague of man and that of mice. The same specific agent is the cause of each. It is communicable from mouse to man and vice versa. Either one or the other may be the vehicle of contagion from place to place. Although the transference of infection from a sick man to a healthy man does occasionally occur, the mouse (or rat) seems to be the chief and almost necessary agent of the expidemic diffusion of plague."

**Childbirth with Savage and Civilized Women.**—The labors of savage women are known to be safe and easy. How does civilization render labor difficult? Dr. Reid holds that heredity is largely responsible; that women with small pelves tend to have daughters with a like peculiarity, and that the individual born with a large or small head has a tendency to transmit to his or her children a similar cranial formation. When a savage woman has a small pelvis or a large-headed child she generally dies in labor, and thus, generation after generation, narrow hips and large heads are eliminated, while the right proportion between head and pelvis is secured. In civilized countries many small-hipped and large-headed children are annually preserved. If these perished as they would among savages, the average difficulty of labor in the next generation would be appreciably ameliorated. But, as Dr. Purslow (Birmingham) pointed out, the difficulty of labor in civilized women was often due, partially at least, to deficient power of the expulsive muscles, the result of the use of corsets and the want of exercise. Posture may also to a certain extent be responsible Savage women almost invariably assume the squatting position. If Dr. Reid's deductions are as sound as they are logical, there will be a large and increasing field for the gynæcologist of the future.—*English Medical Review of Reviews.*

**The Conditions of Health of Ladysmith and Pietermaritzburg.**—The British Army Medical Report for 1897 gives some information regarding Ladysmith and Pietermaritzburg which has some points of interest, but the conditions have no doubt undergone considerable change since Ladysmith was occupied as a new military station in May of that year. It is described as an exposed camp about two miles west of the town. The soldiers were then under canvas and exposed to a good deal of discomfort, owing to dust storms in windy weather and the muddy and swampy state of the ground during wet days. Huts of wood and iron were then in process of construction and have since been completed There was at that time no proper drainage for the removal of surface water, and a pail system of conservancy was in operation, the contents being deposited about a mile north of the camp. The water was distributed by water carts filled at a large tank connected by iron pipes with the municipal reservoir (fed from the Klip River) situated near the camp. . . . It is mentioned that the health of the camp had not been satisfactory since the previous October, owing to the prevalence of continued fever and enteric fever, dysentery, and ague The possible importance of Ladysmith as a military station had no doubt attracted attention in 1897, although the part it

was destined to play could not then have been foreseen. Still it probably led to the introduction of some important sanitary changes. At Pietermaritzburg enteric fever was said to have been very prevalent, and the sanitary condition of the locality, especially in respect of the prevention of soil pollution, left much to be desired. The water supply is described as being scarce, but a new water tower was being erected in 1897 to remedy this. The hospital arrangements were said to be inadequate to the requirements; and as the available space in the hospital grounds was occupied by marquees, and the cavalry barracks were utilized as hospital wards, the accommodation afforded in permanent buildings seems to have been insufficient at that time. This, however, is not a matter of any great importance so long as there is plenty of accommodation available under canvas.—*London Lancet.*

**Alcoholism in Great Britain.**—Dr. St. Clair Shadwell, speaking on the English Inebriates Act, 1898, says: "We find that in England in 1891 there were registered as dying from chronic alcoholism, 857 males and 643 females; cirrhosis of the liver, males 2,289, females 1,552, giving a total of 5,896 deaths from alcoholism; nor have we in these figures included all the victims of inebriety, yet they show a larger number of deaths registered during the same year than from either enteric fever or diphtheria."

**Low Death Rate at Buffalo.**—The Buffalo death rate last year was 12.24. This reckoning is obtained on the basis of an estimated population of 370,000, the number of deaths from all causes during the year being 4,533. No city in the United States of equal size shows a death rate so low. It is noticeable that nearly all the lake cities were comparatively healthful. Cleveland with a population also estimated at 370,000 had a death rate of 13.62.—*Buffalo Medical Journal.*

**Casualties Resulting from the Shelling of Mafeking.**—It is good to observe that the inhabitants of Mafeking and Kimberley are keeping their spirits up, or rather were at the time this report was dispatched. The resident magistrate at Mafeking, writing on the 17th inst. to the premier of the Cape, reported that the Boers had shelled the town for four hours, the result being that a dog was killed, while from Kimberley a few days later the news came that after a heavy bombardment the only damage done was the breaking of a cooking-pot.

**The Grape Cure.**—No. 35, *Gazeta Medica Lombarda*, contains an account of the grape cure, taken partly from the *Journal de la Santé*. This method of treatment is recommended by Dujardin-Beaumetz and others for cases of dyspepsia, especially when accompanied by constipation and in the gouty. It is also valuable in chronic diarrhœa of dysenteric origin, and Tissot tells a story of a regiment of soldiers decimated by dysentery which vanished in a marvellous manner on encamping among vineyards full of ripe grapes. Chronic cystitis is benefited by the alkaline carbonates developed by the vegetable acids of the fruit, but in such cases care must be taken that the grapes are not sour. Cardiac affections are relieved by the laxative and diuretic action, while almost all patients are benefited by the fresh air, exercise, and early rising which the rules of the "cure" involve. Grapes grown on volcanic soil are said to have a more markedly stimulant and diuretic action than others. As to the amount Dujardin-Beaumetz recommends patients to take as much as they possibly can without exciting disgust, while others advise a gradual increase to a daily maximum of four kilos. The duration of the cure is one to three months.—*Medical Magazine.*

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended December 15, 1899:

| | | Cases. | Deaths. |
|---|---|---|---|
| **Smallpox—United States.** | | | |
| District of Columbia, Washington | December 2d to 9th | 2 | . |
| Kansas, Arkansas City | November 27th to December 2d | 14 | 1 |
| Columbus | November 27th to December 2d | 1 | |
| Lawrence | November 27th to December 2d | 6 | |
| Peoria | November 27th to December 2d | 1 | |

### ETHERIZATION: THE MEANS WHEREBY THE QUANTITY WAS REDUCED FROM ONE THOUSAND TO ONE HUNDRED GRAMS PER HOUR: WITH ESPECIAL REFERENCE TO THE POSITION OF THE HEAD AS AFFECTING RESPIRATION.[1]

BY A. ERNEST GALLANT, M.D.,

FORMERLY ANÆSTHETIST TO THE ROOSEVELT HOSPITAL, GYNÆCOLOGICAL DIVISION; AND (AS INTERNE) TO THE NEW YORK CANCER HOSPITAL, THE SLOANE MATERNITY HOSPITAL, NEW YORK, AND THE ST. JOSEPH'S HOSPITAL, PATERSON, N. J.

IT has been very gratifying to note the number of excellent articles which have brought before the profession the need of well-trained anæsthetists. Every practitioner, at one time or another, is sure to be unpleasantly brought face to face with this truth, and to realize that he has leaned upon a broken reed.

Never can the writer forget the time when as a second-year man he was called upon for the first time to administer an anæsthetic. Without advice, without training, without even a fair knowledge of the action of the poisonous drug, yet anxious and willing to learn the art, it was with much trepidation he accepted the "towel cone" and at the command of the "house" poured on and crowded the ether, "blind leading the blind." In Roosevelt Hospital it was then a daily practice to use 1,000 gm. or more per hour. Much was wasted, and the patients were literally "drowned" in ether, and must have experienced a corresponding degree of shock. The last annual report of this hospital announces the appointment of an "official anæsthetist," and I hope that under his tuition much of this reckless waste and woeful extravagance will be done away with.

While on this subject of trained anæsthetists, it may not be out of place to state that not only every undergraduate medical student and every hospital interne, but every nurse in training should be drilled in the practical details of anæsthesia. Every surgeon, every gynæcologist, every obstetrician—ay, every general practitioner can recall the time when he has found it necessary to call upon the nurse to "hold the cone" or to give chloroform. Have we any right to jeopardize the lives of our patients in this reckless fashion?

Methinks I hear, in one loud acclaim, "No! No!"

Professor Macewen, at the Royal Infirmary, Glasgow, requires his own students to pass a written examination, to give evidence as to their thorough acquaintance with the physiological actions upon the human being of the principal anæsthetic agents, as to the manner in which fatal issues arise, and how these may be averted. Then each is required to administer, under the eye of a competent teacher, an anæsthetic to patients, on at least twelve occasions. If the candidate proves worthy in both examinations, he is granted a certificate of proficiency in anæsthesia.

How often we hear, in cruel jest, "The operation was a great success, but the patient died." Was this melancholy result due to the anæsthetic, *per se*, or to unskilful administration?

Successful anæsthesia depends upon: (1) The preparation of the patient; (2) the administration of the anæsthetic; (3) the early recognition of and means for overcoming accidents during anæsthesia; (4) the after-care of the patient.

**The Preparation of the Patient** cannot be thoroughly accomplished in less than a week, to afford time to ascertain the real condition of the (*a*) kidneys; to evacuate entirely the (*b*) intestinal tract, and give the bowels at least twelve hours' rest just before operation, to minimize painful peristalsis, which so often follows handling of the abdominal viscera. The (*c*) food must depend largely on the activity of digestion, and the general condition of the patient. Food and liquid exhibited twelve to twenty hours before anæsthesia is sometimes vomited, in an wholly undigested state; digestion being at a standstill, probably owing to nervous anticipation and dread of operation. (*d*) A good night's rest is without doubt one of the best means of fortifying a patient against subsequent shock, and can often be induced by a hot ammonia bath, followed by a rub-down with weak alcohol. Too little attention is paid to the observation of the (*e*) character of the pulse and action of the heart before operation, by which to compare its work during anæsthesia and after the operation is over, and this neglect leads to unnecessary stimulation and over-driving a heart which is doing its average best.

**Administering the Anæsthetic.**—The choice of anæsthetic must depend largely on the judgment and inclination of the surgeon, and the result of the study of the kidneys, heart, and lungs of the patient.

Nitrous oxide has now a well-established place as the most agreeable and safe anæsthetic for diagnostic examinations and minor operations, and in the practice of the writer has replaced all others for curettage, circumcision, excision of cysts, reduction of dislocations or fractures, etc. It will no doubt surprise many to learn that in the hands of one familiar with its use its action can be continued from one-half to one hour. For rapid and pleasant induction of anæsthesia, preceding ether, it stands as an ideal drug. The complete apparatus including cylinder, bag, and inhaler is put up in a box weighing thirty-five to forty pounds, which can be carried in the hand. The empty cylinders can be exchanged for full ones, without other expense than the cost of the gas.

Ether. The inhalation of ether is made disagreeable only by those who brutally insist on the so-called "rapid" method, accomplished by crowding the cone tightly over the face, and holding it there, in spite of the most strenuous efforts of the patient to secure a comfortable inspiration. It would be a pleasure to the writer to anæsthetize such an "enthusiast" after his own plan, as the only means of teaching the error of his way.

The cone. The aim of every anæsthetist is to induce and maintain a uniform degree of anæsthesia with a minimum quantity of ether, and avoid nausea, vomiting, and shock. After many experiments with the various forms of cones, the best results have been obtained by a modified Allis' inhaler.

[1] Read before the Harlem Medical Association, October 9, 1899.

1. The rubber sheath has been made extra long, eight and one-half inches, (*a*) to increase the air space above, and the nose space below; and (*b*) by folding in the upper edges (Fig. 1) we prevent the escape of ether, and administer it in a more concentrated form.

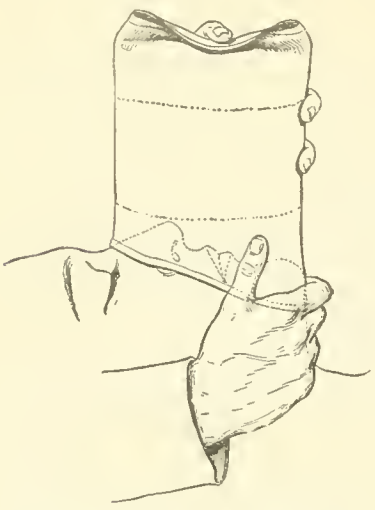

Fig. 1.—Cone Adjusted to Face, Ample Air Space above, and Nose Space below Frame. Right hand supporting chin, to prevent relaxation of jaw and prolapse of the tongue. Left hand folding top of cone to increase the amount inspired.

2. Fold a piece of gauze, four to eight thicknesses, over the end of the metal frame (Fig. 2), and invert it into the sheath, so that the diaphragm will lie just above the nose (Fig. 1); this prevents ether from splashing through into the nose or mouth of the patient.

3. Into the cavity thus formed, place three-quarters of a yard of gauze, bunched up like a handkerchief (Fig. 2). Absorbent cotton and sea-sponges have a great affinity for aqueous vapor, soon become saturated with moisture from the breath, and fail to take up the ether poured thereon. Coarse meshed gauze, on the other hand, when loosely placed in the cone allows the warm breath to act upon the cold ether, raises the temperature of the inhaled air more nearly to the normal, is less irritating to the pulmonary mucous membrane, and reduces the liability to post-operative bronchitis.

4. Through the open top, ether in drachm doses can be added at frequent intervals, without removing the cone. The free admixture of air guards against oversaturation; the gauze diaphragm prevents vomiting into the cone; in prolonged operations, the loose gauze can be readily replaced, and, last but not least, the tedious lacing of the frame is avoided.

"Surgical degree." "The object of anæsthesia is to suspend the action of the centres which have to do with sensation and motion, while leaving the respiratory and cardiac centres intact." In other words, the degree of anæsthesia must be profound enough to abolish sensation with relaxation of the voluntary muscles, generally designated the "surgical degree." In abdominal operations it is essential that the recti be relaxed.

Position on the table. It will be found much more convenient for the anæsthetist to etherize his patient upon the operating-table. Having removed false teeth, finger-rings, and ear-rings, place the patient in the dorsal position upon the table, with a pillow under the head—not under the shoulders—just thick enough to raise it to a comfortable level (Fig. 3).

Deep breathing. As but few persons are accustomed to the effort involved in fully inflating the lungs, it is well, before bringing the cone near the face, to insist on a few minutes' practice in "taking long breaths." Saturate the gauze in the cone with ether, and, in order to reassure the patient of its harmlessness and to illustrate how it must be done, place it close to your own face, and take a long, deep inspiration.

Self-administration. Hand the cone to the patient, and encourage him to bring it nearer and nearer to his face. If he complains that it is too strong, repeat the suggestion of Dr. George F. Shrady, to "blow it away," thereby insuring full expiration and inspiration, and rapid saturation of the blood with ether. In two or three minutes the hands will begin to relax their hold on the cone, when it must be taken up by the administrator and adjusted closely to the face. Fold in the top of the cone (Fig. 3) to increase the amount inspired. By applying his nose to a corner of the cone, the anæsthetist can estimate the quantity of ether still in the cone.

Position of the anæsthetist. At this stage, sit down at the head of the table, resting your elbows one on either side of the patient's head, to prevent swaying from side to side (Fig. 3).

A struggling patient can be pinned to the table if an assistant will place one hand on each arm just above the elbow, and throw her whole weight thereon (Fig. 3). If two assistants are at hand, station one on each side of the table; let them place one hand on the patient's shoulder, the other grasping the humerus just above the elbow, and weight him to the table. In this position it is impossible for the patient to reach the cone, raise his body, or slide off the table. Struggling will hasten the desired end.

**Accidents during Anæsthesia.**—Prophylaxis. By thoroughly emptying the bowels of fæces, we can minimize fermentation and abdominal distention, and avoid distressing pressure on the heart and lungs. The ingestion daily of from two to three quarts of water (a glassful every two hours) will have an excellent effect on the kidneys and intestinal tract, and also tend to raise the blood-pressure.

Heart. From our ante-anæsthesia observations of the pulse—radial and temporal—and the color of the skin, we are able to note any change in the action of the heart. By pinching the lobe of either ear, the refilling of the capillaries and return to normal redness affords reliable means of determining the condition and activity of the circulation.

Heart stimulants. A small dose of morphine (gr. $\frac{1}{12}$ or $\frac{1}{8}$) hypodermatically, fifteen to twenty minutes immediately preceding etherization, will have a quieting effect on respiration, stimulate the heart's action,

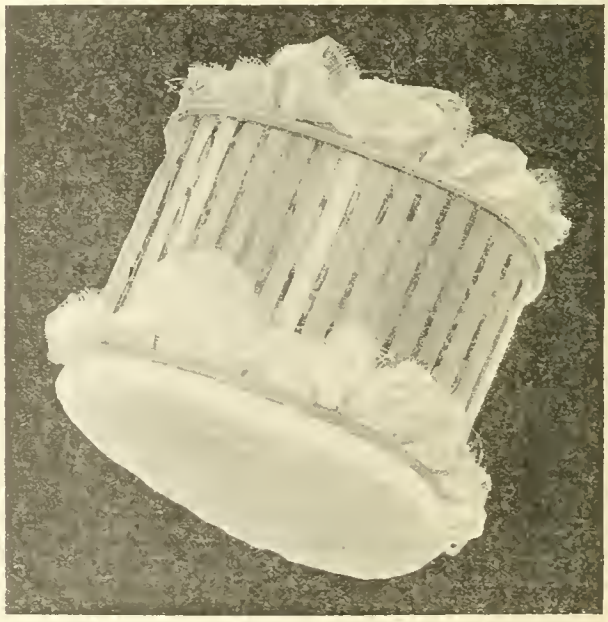

Fig. 2.—Gauze Diaphragm Adjusted to Frame of Allis' Inhaler. Cavity filled with loose gauze, ready for introduction into the rubber sheath.

and unlike larger doses (gr. $\frac{1}{6}$ to $\frac{1}{4}$) will lessen post-operative nausea and vomiting and diminish the quantity of ether necessary to maintain anæsthesia. Heart weakness may be met by the hypodermatic use of strychnine (gr. $\frac{1}{30}$), tincture digitalis (♏ x.–xx.), or brandy.

Loss of blood or shock from prolonged operation must be overcome through enemata of hot (120°–130° F.) saline solution (℥ i. to O i.), to which may be added two to four ounces of brandy. The effect of such an injection will be almost marvellous. Saline infusion during an operation or at its close, before consciousness has been restored, has done excellent service under similar circumstances.

Respiration. The most troublesome and annoying feature during anæsthesia is the action of respiration. When the cone is gradually brought near the face by the patient himself, little difficulty is experienced, but as soon as the mask is fitted over the nose and chin, and the air fully charged with ether, a choking sensation occurs, and the patient will struggle violently to remove the cone. At no time is better judgment needed than at this stage. Raise the cone, allow the patient to take a full inspiration, and then quietly replace it with the injunction to "blow it away." From this time on the cone should not be removed from the face until the surgical degree has been reached.

Fig. 3.—Correct Position of Pillow, Head on a Comfortable Level. Proper position of anæsthetist, patient's head immobilized between elbows; right hand supporting chin and cone, left hand closing top of cone; nurse grasping arms just above elbows, pinning struggling patient to the table.

Stertor. Our knowledge of the conditions which cause stertor or noisy breathing have been greatly amplified by the work of Robert L. Bowles, M.D., F.R.C. P. London.[1] Therein he tells us: "It is well known that the cavity of the pharynx, having a fixed boundary only posteriorly, may have its capacity materially affected by the ever-changing position of its sides, of the soft palate, the tongue, and the larynx. The tongue, being attached to the lower jaw by its mucous membrane and its muscles, has its relations with the surrounding parts altered as the mouth is opened or closed. With the mouth closed, the horizontal portion or body of the jaw forms nearly a right angle with the spinal column, from which the symphysis is then at its greatest distance. When the mouth is opened by the dropping of the jaw, the symphysis describes the arc of a circle and approaches more nearly to the spine, where the posterior wall of the pharynx is attached. The tongue, having its chief attachment to the symphysis, would consequently be drawn away from the pharynx in the former case, and allowed to rest in contact with it in the latter. This, if not true in every case, is at least true in some.

"When the mouth was opened and the subject on its back, the road to the larynx was completely obliterated, in consequence of the tongue resting in contact with the vault of the pharynx, but the obstruction could be removed by hooking the tongue forward. When the mouth was closed, the tongue was lifted from the pharynx, leaving ample breathing space. But even with the mouth closed, if the chin was much bent on the sternum, the base of the tongue was almost in contact with the back of the pharynx.

"The dissections, besides demonstrating the respective positions of the tongue with the open and closed mouth, suggest the necessity of caution being used in raising the head with pillows; for if the head be bent too much forward on the chest, the tongue may lie in dangerous proximity to the pharynx even when the mouth is closed."

Varieties of stertor. "The deep vibrating snore of sleep with the mouth closed depends upon the tongue pressing the velum palati upward and backward, thus narrowing the opening between the nose and the pharynx, the velum vibrating as the air rushes through. Sometimes, when the mouth is partially open, the soft palate drops upon the tongue, and vibrates as the air rushes between it and the tongue."

To either of these noises in which the soft palate is concerned Bowles proposes the name "palatine stertor." The harsh, sharp, husky noise, occurring in apoplexy (or anæsthesia) with the mouth wide open, always arises low down in the pharynx, and depends upon the narrowing of the passage between its posterior wall and the base of the tongue, and as it arises solely in the pharynx, he has given it the name of "pharyngeal stertor."

"There is another variety of stertor which may be

[1] "Stertor, Apoplexy, and the Management of the Apoplectic State." Wood's "Medical and Surgical Monographs," vol. ix., No. 3, September, 1891.

named 'mucous stertor,' as it depends upon the presence of mucus in the bronchial tube.

"Of these three different varieties, that which is named 'pharyngeal' is by far the most dangerous, for the greater the paralysis (relaxation) the more effectually does the tongue block up the passage, and each inspiration only adds to the obstruction by sucking the tongue lower down into the pharynx. Its danger is, however, not due alone to the gradual impediment it offers to respiration, but also to the fact that at any moment this impediment may become absolute and cause death by suffocation. We may observe this in the snoring sleeper, who, after drawing several inspirations with evident effort, at last comes to a sudden check from having been gagged by the tongue falling back. This will rouse him from his stupor, and he will then sleep on quietly until the same thing recurs from his deepening sleep."

Position of the head to prevent or overcome stertor. To prevent mucus collecting in the bronchial tubes, and to stop "mucous stertor," turn the patient's head to one or the other side, and allow the saliva and mucus to run out at the corner of the mouth.

From the foregoing we learn that in order to prevent "pharyngeal stertor" the head must lie in such a position as will not bend the neck too far back or approximate the jaw too near to the sternum (Fig. 1). Knowing that pharyngeal stertor is due to the too close approximation of the paralyzed tongue upon the posterior pharyngeal wall—really against the cervical vertebræ—by adjusting the head a little higher or a little lower we can afford relief. Turning the head to one side will in some instances give relief. In others it is necessary to lift the jaw well up, not in the usual barbarous fashion, but by embracing the chin in the hollow of the hand (Fig. 1), being careful not to bend the head backward and so arch the cervical vertebræ forward, for by so doing we increase rather than relieve the difficulty. When, during the administration of an anæsthetic, especially chloroform, the patient suddenly ceases breathing and becomes deadly pale, the jaw drops and the tongue touches the teeth, we may be sure the tongue is at fault. To Dr. H. A. Hare, of Philadelphia,[1] we owe the proof by demonstration, that in order to open the larynx and give free entrance to air the tongue must be pulled upward toward the nose. This can be accomplished by the use of forceps, a hook tenaculum, or, better still, by running the finger well down the dorsum of the tongue and pressing it forward toward the teeth, when a deep inspiration will result, and the patient will breathe naturally.

Cyanosis. A deep purplish darkening of the face, and the escape of dark blood from the field of operation, indicate that the patient is not inhaling enough oxygen; really a condition of temporary asphyxia from accumulated mucus, foreign body in the trachea, or obstruction by the tongue, and which can be readily relieved by removing the cause. Cyanosis is most often met with in stout, short, thick-necked people, and necessitates a more careful adjustment of the head, and close attention to the general condition.

Vomiting. The precautions given as to food and diet must be observed, and anæsthesia maintained at the surgical degree to prevent vomiting. If efforts at vomiting do occur during etherization, turn the head to one side, wipe out the mouth, and, during the interim, crowd the ether so as to dull the vomiting centre and prevent its recurrence. Inhalation into the larynx or trachea of solid particles of food is almost positively fatal.

Artificial respiration. Failure of respiration demands the application of artificial respiration. While Sylvester's method is the most popular, unless the tongue is held "well forward toward the nose," no air can enter the lungs. Marshall Hall's method affords the most natural means, as in the side position the tongue falls forward, mucus runs out of the side of the mouth, and respiration is unimpeded.

Oxygen by inhalation, as a stimulant to the heart and respiration, is of great benefit in plethoric, short-necked people, who seldom breathe well during anæsthesia. Oxygen may be applied directly to the mouth, to the nose, or introduced beneath the cone.

**After-Care.**—Without enumerating the ordinary measures, there are four points wherein the writer differs from the usual procedure in the care of patients recovering from anæsthesia, viz.:

1. Hot water. Ever since a cœliotomy patient, under my care, sat up in bed, two hours after operation, emptied the contents of a hot-water bag into her stomach, and recovered, it has been my practice to give hot water *ad libitum* as soon as the patient is conscious enough to ask for a drink. It allays gastric irritability, quenches thirst, and if vomited really washes out the stomach. Its early use also has a good effect on the kidneys and intestines.

2. Nourishment. Milk, with or without lime-water, is given as soon as the stomach is quiescent. Starvation does not strengthen a weak heart, nor aid recovery from loss of blood or shock.

3. Position of the patient. As soon as the dorsal decubitus becomes at all irksome, turn the patient on the side, and a restful sleep will follow.

4. Intestinal distention or paresis usually begins during the latter part of the first day, and soon becomes a source of great discomfort. If not relieved by high enemata, at once resort to friction along the colon; beginning at the right iliac fossa, pass the hand up the ascending, across the transverse, and down the descending colon, slowly repeating this manœuvre for fifteen or twenty minutes.[1] This will result in free discharge of gas from the rectum, give immediate relief, assure us that there are no intestinal kinks, and that the bowels will move whenever it is deemed desirable.

60 West Fifty-sixth Street.

## THE TREATMENT OF SEROUS EFFUSIONS.[2]

By CHARLES H. LEWIS, M.D.,

NEW YORK,

VISITING PHYSICIAN TO COLUMBUS HOSPITAL; ASSISTANT VISITING PHYSICIAN TO ST. VINCENT'S HOSPITAL.

The treatment of serous effusions appeals to a large portion of the medical fraternity, and is an appropriate subject to bring before an association of this kind in which specialists in every branch of medicine are wont to congregate. The general surgeon meets an accumulation of serum in the synovial sacs of the joints, and the bursæ of the tendons; the neurologist in the meninges and ventricles of the brain and cord; the genito-urinary specialist in the tunica vaginalis, and the specialist of internal medicine, otherwise known as the general practitioner, in the peritoneum, pericardium, and pleura. Notwithstanding the wide distribution of the serous cavities in the body—they being present in head, trunk, and extremities—each or all may contain an abnormal amount of serum in disease of the heart, kidney, or blood. Indeed, such transudations may waterlog every tissue of the body.

In the following paper I shall exclude all such effusions, and limit myself to the exudations following local inflammation or irritation, and for the most part use the pleura as a type of its class. A basement membrane of connective tissue, interspersed with few

[1] See Mathew's Medical Quarterly, vol. iii., July 18, 1896.

[2] Read before the Hospital Graduates' Club, November 23, 1899.

elastic fibres, paved with a single layer of endothelial cells, traversed by a plexus of vessels, nerves, and lymphatics, the latter terminating in open mouths between the cells, is the histology of a serous membrane. This membrane, folded on itself so as to form a blind sac, encloses a serous cavity. In health, the plasma of the blood in limited quantity passes through the wall of the capillary, undergoing certain changes in its transit, moistens the internal surface of the serous sac, makes its exit through the minute openings of the lymphatics, and returns again, by the way of the thoracic duct or right lymphatic trunk, to the blood. The process of evacuating the serous sac of its contained lymph is facilitated in the case of the pleura by the respiratory movements of the lungs and by the valves of the lymphatics. It is not unlike the mechanism of a suction pump. Normally no serum flows into the cavity beyond that which the lymphatic pump can easily remove. The inflow from the blood current equals the outflow by the lymphatic stream. Such is the physiology of the serous sac.

Under irritation, chemical, bacterial, or traumatic, the capillary vessels swell and become congested, the connective-tissue cells proliferate, an increased flow of plasma, plus leucocytes, fibrin, red corpuscles, and bacteria, swells the stream which pours into the serous sac. The lymphatic pump is overtaxed. Fibrin clogs the mouths of the absorbents, and an effusion obtains, serous, sero-fibrinous, fibrinous, sero-sanguinolent, or purulent, according as each element preponderates. There is no "dry" pleurisy without some serum, and the clearest serum contains some fibrin, blood and pus cells. Degree of irritation then, rather than kind, characterizes the exudation of a serous membrane. The same pathology applies to all cases.

Such being the mechanism of the serous exudate, from whence springs the irritant of the capillary, for this is the initial step in the process? The clinical history as a rule gives us a working hypothesis. A previous or coincident condition justifying the presence in blood or tissues of the pneumococcus, tubercle bacillus, strepto- or staphylococcus, points unmistakably to these germs or their toxins as the probable irritant; with less directness and exceptionally the gonococcus, typhoid bacillus, and bacillus coli communis, harmless enough in their own habitat but pathogenic outside, may offer an adequate explanation; for these germs have all been found in pleural effusions. The toxins of syphilis and rheumatism, temperature changes, and traumatism, from the sequence of events, are worthy of consideration. An antecedent history embracing any of these conditions, attached to a patient with slight cough, localized pain, dyspnœa, and some rise of temperature, outlines a clinical representation of pleurisy with effusion. A displaced heart, an increased perimeter of the chest, or, better, a change in its shape, along with the well-known signs of auscultation and percussion, fill in the outlines, add color, and complete the picture. We have, then, to deal with a compressed—carnified—lung, and a serous sac distended with fluid.

Such a condition presenting, the first indication of treatment is removal of the fluid, and restoration of the cavity and lung to their normal relations, and to effect this as speedily as possible. I am not unmindful, in this connection, of Murphy's recommendation in cases of pulmonary tuberculosis, namely, to bring about identical relations of lung and pleura through the introduction into the pleural cavity of nitrogen gas. So far as I am aware, however, no other authority has advocated this measure, and West and others denounce it as an erroneous principle, which it seems theoretically to be.

In emptying a pleural cavity of fluid, two methods may be employed: first, aspiration; second, absorption through the lymphatic channels. So far as rapidity is concerned, aspiration as recommended by Bowditch, forty years ago, furnishes an ideal method. With modern asepsis and average care, the operation is entirely free from danger. The objection is the often rapid recurrence of the fluid, and the consequent necessity of a frequent repetition of the operation. On the other hand, in my experience, spontaneous absorption by the lymphatic stream, when effective, leads to permanent results. The absorptive power of the lymphatic sponge, however, even when drained through the bowel, kidneys, and skin, and dried by the least possible injection of liquids, is slow, desultory, and often negative. It is not infrequent to observe fluid remaining unchanged in a pleural cavity for weeks and months, all of which time the patient is undergoing a rigorous and enervating course of cathartics, diuretics, and diaphoretics, and then note its abrupt recession and comparatively rapid disappearance. No recurrence follows, but the patient often finds himself face to face with a pulmonary tuberculosis, with which the deteriorated state of his long compressed lung and his own weakened general condition render him unfit to cope successfully.

In other cases, the serum is taken up by the lymphatics promptly and energetically, under eliminative, salicylic, iodide, or no special treatment. The pleural surfaces meet and are firmly and permanently glued together. The patient recovers with thickened and adherent pleural walls. The sac is often changed to a connective-tissue membrane of leathery consistence. No further encroachment of serum is to be apprehended, and, with the exception of a possible subsequent slight contraction, the chest is to all intents and purposes normal. Adhesion of the pleural surfaces is generally found at autopsies when death has occurred from other than chest diseases (eighty per cent. according to Dr. F. Ferguson); and in cases of pleural effusion it is a "consummation devoutly to be wished."

It was to imitate nature in her successful methods as just sketched, that the work incorporated in this paper was undertaken. I am not sure but that if aspiration consumed as many hours as we ordinarily employ minutes, the pleural surfaces would adhere with the same pertinacity and permanence as those in spontaneously absorbed effusions. Nature, however, manages better than art, and not only removes the fluid, but at the same time finishes her work by exuding a cement substance in appropriate quantities, and in favorable locations. She does not, for reasons best known to herself, work uniformly, but, as is well known to all, follows receding effusion by fits and starts, perhaps regulating the amount of absorption to the amount of fibrin she can furnish to glue the surfaces together, as they meet after the subsidence of the liquid. For what shall it profit a man if he lose all the serum, and gain no fibrin?

Absorption if possible, if not aspiration, is the accepted modern treatment of pleural effusions.

The therapeutic resources ordinarily recommended for facilitating absorption are uncertain in their action, and debilitating in their effects. Diuretics and counter-irritants have had their day; hydragogue cathartics drain fluid from the vessels, but carry no assurance that the latter will recoup themselves from the reservoir in the pleura; diaphoretics possess all the disadvantages of hydragogue cathartics with none of their advantages; iodides and salicylates serve as forlorn hopes; antiphlogistics are antiquated and unscientific; so that the patient, as a rule, emerges from a longer or shorter course of internal medication, and comes to the aspirator, a sadder and weaker man. Here, too, no assurance can be given that there will

be no return of the fluid, and if repeated aspirations are necessary, "the last state of that man is worse than the first."

In studying the course of serous effusions, it has seemed to me that if we could secure a general deposit of fibrin on the pleural surfaces, and then aspirate, adhesion of the walls of the sac would follow, and a resultant obliteration of the cavity. This, as nature has taught us, is the goal to strive for. Different astringents have been injected into the serous cavities with the view of promoting adhesions, but, so far as I am aware, these injections have been employed after removal of the fluid; consequently but a small part of the serous membrane comes in contact with the irritating solution, and but a small part is coated with the adhesive fibrin. Dr. Janeway[1] has thrown into pleural effusions of a suspected tuberculous nature two to five drops of creosote in alcoholic solution. No harm resulted, and in some cases much improvement. Absorption took place, and no pulmonary tuberculosis followed. In reference to one case he adds: "Had it not been for the success attained, this case would have been regarded as undoubtedly tuberculous." He mentioned this method of treatment in connection with remedies for tuberculous pleurisy, and not for its effect on fibrin formation, or absorption of the fluid.

That astringent injections, in animals at least, will produce artificial exudative pleurisies, and that the character of the exudation varies directly with the strength of the irritant, is shown by the experiments of Delafield and Prudden.[2]

In order safely to throw a feebly irritating solution into a serous effusion, so that the former may come in contact with the entire surface which the serum bathes, certain conditions must be fulfilled: First, the irritating material must form an easy and permanent solution in the vehicle employed and in the serum; second, the reaction and specific gravity of both fluids must correspond as closely as possible; third, the material injected must be antiseptic or easily rendered aseptic; fourth, the volume of the fluid in the sac must remain unchanged. About three years ago I made some experiments in this line, with iodine in the form of the tincture, permanganate of potassium, and the aniline dyes fuchsin and methylene blue. Solutions of these were made in a decinormal salt solution, and each was mixed with a definite quantity of fresh human serum. As a result of these experiments I found that the tincture of iodine, while irritative and aseptic, mixed uniformly only after considerable agitation; and the uniformity of the resultant mixture was but transient. The others were to a less degree open to the same objection. In order to obviate this defect if possible, I next approximated a salt solution to the specific gravity of the serous exudation. This has been found to differ somewhat, according to different observers. Gee (in Allbutt's "System of Medicine") gives it as 1.018–1.024, although it may go as low as 1.006. Dickinson in the same volume finds an average gravity of 1.013. An average of a small number of serums tested by the house physician of Columbus Hospital recorded a specific gravity of 1.018. A 3.5 per cent. salt solution in distilled water registers a specific gravity of 1.020. Fuchsin in this solution is but slightly soluble, and was discarded on that account. There remained potassium permanganate and methylene blue, both of which deeply and uniformly stained the salt solution with their respective dyes. On adding these solutions to freshly drawn human serum, however, the potassium permanganate became at once decolorized, while the blue solution, after considerably less agitation than in the case of the decinormal saline solution, imparted to the mixture a uniformly deep blue color. This, however, on standing for some hours, did not preserve its original uniform tint. As the result of these experiments, the blue aniline seemed to be the proper material to use, but the salt solution did not appear to be the ideal vehicle.

Methylene blue is antiseptic, anodyne, has diuretic properties, is easily detected in the urine, and imparts a color not found in any bodily secretion, physiological or pathological. Bearing these properties in mind, I withdrew about three and one-half ounces of serum in a case of pleural effusion, and ventured to replace it with the same amount of salt solution (specific gravity 1.020), in which twelve grains of methylene blue were dissolved. The results in this case were not altogether satisfactory. The pain was considerable, and hypodermic withdrawals at different points over the affected chest gave a variety of blue tints, or no blue color at all. Absorption took place in a period somewhat less than usual, but the clinical condition during this time was not such as to encourage another trial. While withdrawing the serum to make room for the salt solution, the idea occurred to me to use the former as the solvent, and, after taking up the blue, to return it again to the cavity. By such a procedure, every essential would be fulfilled. As I had already determined, serum readily dissolves methylene blue in about one to fifty parts. The reaction and specific gravity would obviously agree, being a part of the whole; if no infection occurred during the trip, its condition as to sterility would be as good as before—which we have seen is not always the best; and finally, the amounts borrowed would be paid in full, so that no change in volume would result. It was expected that the respiratory movements and the operation of injection would produce sufficient agitation in the chest cavity to make a uniform mixture of the two serums.

In this connection, the action of living serum, if we may so term it, or some of its constituents, on methylene blue is most interesting. If we introduce hypodermatically methylene blue into the serum of a surface blister—which can easily be done by penetrating the blister through the healthy skin, withdrawing some serum into the syringe containing the blue powder, and then reinjecting—a uniform blue color at once appears through the translucent skin. Some hours later, the color assumes a greenish tinge, and the next day the wrinkled skin shows a diminution of the fluid. If we withdraw serum from the same blister into a sterilized test tube containing methylene blue, the color remains unchanged provided no infection is present. I have preserved this blue-tinted serum in such test tubes for over three weeks without the slightest change in color. Bacterial infection will, however, sooner or later destroy the tint. In the same way, serum in a serous cavity decolorizes the aniline blue or exhibits a greenish tinge (chromogen) after a few hours; but in a cavity outside of the body preserves the color for weeks. Whether this action is due to leucocytes, fibrin, or some unknown constituent added from the blood, I am unable to say. Certain it is, that the same fluid inside and outside the body acts differently on the aniline. As I found subsequently in my injections into serous sacs, a part of the blue is rapidly taken up and excreted by the urine; yet much remains, although the color does not indicate it, and its presence can easily be demonstrated by adding acetic acid and heating.

The method which I employed for withdrawing the fluid, making the solution, and reinjecting into the serous cavity is practised by means of a large aspirating syringe, with a needle of medium calibre, and fitted with asbestos piston and washers. A rubber

[1] Transactions New York Academy of Medicine, 1893.
[2] "Pathological Anatomy and Histology."

tube is attached to the outflow tube of the syringe, and extends into a glass graduate of a capacity of 100 c.c. or more, which holds the methylene blue. A glass rod for mixing the blue and serum is inserted into the vessel alongside the rubber tube, and the entrance is then plugged with sterilized cotton. The whole outfit before use is easily sterilized by heat. If the sterilization is thorough, infection of the serum on the round trip from sac to vessel and return, is impossible. Ordinary care renders the needle clean. The methylene blue, being put into the graduate before sterilization, is itself sterilized. It is, however, antiseptic, and I have never been able to get any growth from it in culture media, even when coming from sources which would contaminate non-antiseptic materials.

I have used the method of treatment just described in twenty cases of pleurisy with effusion, and synopses of the histories follow. All the work incorporated in this paper was done in Columbus Hospital during the past three years, with the active co-operation of the various internes, without whose aid, which I here gratefully acknowledge, the investigations would have been impossible. The great number of urinary examinations, of hypodermatic withdrawals at fixed periods, observations and examinations of fluid withdrawn, entailed a very considerable amount of labor and presupposed a constant surveillance over the patients.

Case I.—G. S——, male, aged twenty years, admitted January 20, 1897, with rheumatism, one month prior to present attack, which began one week before admission. At present he has pain, cough, and dyspnœa, with physical signs of right pleural effusion. Apex beat in nipple line; right chest sixteen inches, left chest fifteen inches. Temperature, 99.8° F.

January 22d: Injected methylene blue, gr. xii. in 100 c.c. (3¼ ounces) serum.

January 25th: The needle was introduced for aspiration purposes. No fluid was found on repeated introductions. The urine is greenish in color, and of increased quantity.

January 26th: Respiratory sounds are returning.

January 30th: The urine is still green. The apex beat is normal.

February 1st: Respiratory and voice sounds are returning.

February 3d: The urine is amber colored. The patient has some joint pains, otherwise he feels well. The chest perimeters are equal.

February 11th: There is no recurrence of the effusion. Discharged cured.

This patient could have left the hospital on February 3d, twelve days after the injection, except for the joint pains. His detention also gave me an opportunity of noting whether or not there was a recurrence of the effusion. Much to my surprise, the result in this case looked toward a rapid absorption of the serum after the addition of the aniline. I did not, at that time, attribute this to the presence of the methylene blue, and I am still of the opinion, from the physical signs presenting, that, although greatly diminished in amount, some fluid was present three days after injection, and the failure of the needle to show it was due to clogging from exuded fibrin.

Dr. A. A. Smith first publicly drew attention to the fact that the abstraction of a small part of the serous effusion was often followed by the rapid disappearance of the whole. In this case, no fluid was withdrawn, but probably more than a drachm remained in the syringe and needle, and to this circumstance I attributed the sudden subsidence of the fluid. At that time, I feared the possible injection of air into the pleural sac, and consequently did not empty the syringe as completely as might be. Since then I have learned that air, sterile and in limited quantity, may be thrown into a pleural sac with impunity, as has repeatedly and advantageously been done in the case of the peritoneum.

Case II.—C. A——, male, aged twenty-nine years, admitted February 15, 1897. Previous history immaterial. He had pain in the chest four days before admission. The apex beat was displaced to the sternum, and the ordinary physical signs of left pleural effusion were present.

February 17th: Injected gr. vii. of methylene blue in 80 c.c. (℥ iiss.) serum.

February 19th: Aspirated 109½ ounces of turbid, dark greenish (colored) fluid.

March 11th: Discharged cured.

Case III.—L. J——, male, aged twenty-seven years, admitted May 3, 1897. He had rheumatism six months ago. His present illness has lasted fifteen days. Temperature, 99.4° F. Apex beat in nipple line. He has physical signs of right-sided pleural effusion.

February 6th: Injected gr. v. methylene blue in 50 c.c. (℥ i. ℥ v.) serum.

February 8th: The hypodermic needle withdraws fluid, greenish and rather turbid. The urine is greenish and copious.

February 10th: The hypodermic needle finds no fluid. The respiratory and voice sounds are returning. The dulness is still present.

February 12th: Discharged cured.

Case IV.—M. P——, female, aged twenty-six years, admitted June 2, 1897. Previous history was negative. Present illness began fifteen days ago. Apex beat is three inches to right of normal position. The left chest is half an inch greater than the right chest. Temperature, 102.4° F. A large effusion in the left chest was diagnosed.

June 4th: Injected gr. xv. of methylene blue in 100 c.c. (℥ iii. ℥ ii.) serum.

June 5th: The urine is green.

June 9th: The apex beat is returning to normal position. The chest was aspirated, and forty ounces of greenish turbid fluid were evacuated.

June 10th: The respiratory murmur is returning. The patient is up and about the ward.

June 20th: Discharged cured.

Case V.—M. C——, male, aged fourteen years, admitted June 14, 1897. He had rheumatism two months ago. His present illness began three weeks ago. The left chest is three-fourths of an inch greater than the right. The apex of the heart is displaced toward the right. Temperature, 101.6° F. Diagnosis, left pleural effusion.

June 17th: Injected gr. xv. methylene blue to 100 c.c. (℥ iii. ℥ ii.) serum.

June 18th: Hypodermic shows pale green serum. The urine is green.

June 21: The respiratory murmur is good.

June 27th: Discharged cured.

Case VI.—J. B——, male, aged thirty-two years, admitted June 24, 1897. His previous history is negative. He has been ill twenty days. The left chest is three-fourths of an inch greater than the right. The apex beat is one inch to the right. Diagnosis, left pleural effusion.

June 25th: Injected gr. xv. methylene blue to 100 c.c. (℥ iii. ℥ ii.) serum.

July 7th: The respiratory murmur is about normal. The apex beat is in its usual place. The urine is greenish. The left chest has the same perimeter as the right.

July 9th: Discharged cured.

Case VII.—L. R——, male, aged twenty-five years, admitted September 7, 1897. He has had pain and cough for one month. Temperature, 99.8° F. Diagnosis, moderate effusion on the left side.

September 8th: Injected gr. viii. methylene blue to 40 c.c. (℥ i. ℥ ii.) serum.

September 12th: The urine is pale green. The dulness is slight. Breathing sounds are normal.

September 15th: Discharged cured.

Case VIII.—C. C——, female, aged twenty-eight years, admitted September 17, 1897. She has had a slight chest pain and cough for two months, with chill and increased pain thirteen days ago. The heart apex is one-half inch to the left of the nipple line. The right chest exceeds the left by three inches. Temperature, 101° F. Diagnosis, large right effusion.

September 18th: Injected gr. xv. methylene blue to 100 c.c. (℥ iii. ʒ ii.) serum.

September 19th: The urine is of a dark greenish color. The apex of the heart is in nipple line.

October 8th: Temperature is normal.

October 10th: Out of bed.

October 13th: Discharged cured.

Case IX.—N. T——, male, aged twenty-six years, admitted October 20, 1897. He has had cough and pain for twelve months; has lost flesh. He has night sweats. Temperature, 99.6° F. The heart apex is moved to the right. The left chest is one inch greater than right. Diagnosis, left pleural effusion.

October 23d: Injected gr. xv. methylene blue to 100 c.c. (℥ iii. ʒ ii.) serum. Temperature (evening), 103.2° F.

October 24th: The chest fluid is bluish green.

October 25th: The urine is deep green. The chest fluid is clearer than yesterday.

October 27th: Temperature, 101.2° F. Aspirated forty-seven ounces of rather clear fluid. Acetic acid and heat bring out deep blue color.

November 2d: The respiratory murmur is returning. There is no return of the effusion.

November 5th: Temperature (evening), 99.2° F.

November 8th: Discharged cured.

Case X.—C. P——, male, aged thirty-four years, admitted January 13, 1898. He had a chill fourteen days ago, with cough since the chill. Heart's apex is in the sixth space, three-fourths of an inch left of the nipple line. The right chest is one inch greater than the left. Temperature, 100.4° F. Diagnosis, right pleural effusion.

January 15th: Injected gr. xv. methylene blue to 100 c.c. (℥ iii. ʒ ii.) serum.

January 16th: The urine is green. The fluid is receding.

January 18th: The hypodermic withdraws colorless serum, which becomes blue on adding acetic acid. The urine is green.

January 20th: The heart is returning to its normal position.

January 24th: The heart and respiratory sounds are normal.

February 5th: Discharged cured.

Case XI.—F. L——, female, aged twenty-six years, admitted May 13, 1898. She had a chill nine days ago, with pains over the left chest at the same time. The apex beat is near the ensiform cartilage. Temperature, 100.4° F. Diagnosis, large left effusion.

May 15th: Injected gr. xv. methylene blue to 100 c.c. (℥ iii. ʒ ii.) serum.

May 16th: The fluid is receding, and the apex is moving toward the left. The urine is green.

May 23d: The heart is normal. The respiratory sounds have returned. The urine is still greenish.

June 1st: The respiratory sounds are normal. Discharged cured.

Case XII.—C. B.——, male, aged thirty-five years, admitted September 20, 1898. He had gonorrhœa two years ago. His present illness dates two weeks ago. The apex beat is to the left. Temperature, 101° F. Diagnosis, right pleural effusion (moderate amount).

September 22d: Injected gr. x. methylene blue to 80 c.c. (℥ iiss.) serum. The methylene blue showed in the urine eighteen hours after the injection.

September 29th: The patient is doing well. The methylene blue is disappearing from the urine.

September 30th: Discharged cured.

Case XIII.—C. M——, male, aged twenty-six years, admitted October 3, 1898. His illness is of ten days' standing. The heart is normal. Temperature, 100° F. Diagnosis, small effusion of the right side.

October 5th: Injected gr. viii, methylene blue to 100 c.c. (℥ iii. ʒ ii.) serum.

October 6th: The methylene blue shows in the urine.

October 9th: The patient feels well. The respiratory sounds are returning.

October 12th: Discharged (at patient's own request). He says he feels quite well. The urine is greenish. The respiratory sounds are fairly good.

Case XIV.—C. D——, male, aged twenty-two years, admitted October 12, 1898. He had gonorrhœa and rheumatism (?) two months ago. Heart, apex beat to the left. Temperature, 100.2° F. Diagnosis, right-sided effusion.

October 14th: Injected gr. x. methylene blue to 100 c.c. (℥ iii. ʒ ii.) serum. The methylene blue showed in the urine four hours later.

October 15th: The pain is rather severe. Temperature, 101° F.

October 17th: Temperature, 102° F. Aspirated thirty-two ounces of turbid and blood-stained fluid.

October 19th: He feels well. Temperature, normal.

October 20th: Discharged cured. (This was probably a case of tuberculous effusion.)

Case XV.—G. R——, male, aged thirty-two years, admitted October 24, 1898. He has had a cough four months. Pain over the left side began six days ago. The heart is pushed to the right. Temperature, 100° F. Diagnosis, moderate left-sided effusion.

October 25th: Injected gr. x. methylene blue to 100 c.c. (℥ iii. ʒ ii.) serum. It was found in the urine six hours later.

October 28th: The respiratory sounds are returning.

October 30th: The urine has a small amount of methylene blue.

November 7th: Discharged cured.

Case XVI.—A. G——, male, aged forty-five years, admitted January 14, 1899. He has had pain and cough for ten days. The heart is displaced to the right.

January 19th: Injected gr. x. methylene blue to 100 c.c. (℥ iii. ʒ ii.) serum.

January 20th: The urine is greenish in color.

January 25th: The urine is normal. The respiratory sounds are good. The heart is normal.

January 26th: Discharged cured.

Case XVII.—C. C——, male, aged twenty years, admitted February 2, 1899. He has been ill seven days. The heart is displaced to the left side. Diagnosis, right pleural effusion.

February 4th: Injected gr. x. methylene blue to 100 c.c. (℥ iii. ʒ ii.) serum.

February 7th: The urine is tinged dark green.

February 14th: The heart is normal.

February 16th: Discharged cured.

Case XVIII.—A. U——, male, aged twenty-two years, admitted April 2, 1899. He received a blow on the chest five days ago. Two days later he had a stitch pain and some cough. Now he has cough, restricted movement, and the usual signs of a right-sided effusion.

April 5th: Injected gr. x. methylene blue to 100 c.c. (℥ iii. ʒ ii.) serum.

April 11th: Discharged cured.

Case XIX.—P. C——, male, aged thirty-six years, admitted June 3, 1899. He has had a cough, with

loss of flesh and general bad health for five months. The apex beat is unchanged. He shows physical signs of a small left pleural effusion.

June 5th: Injected gr. x. methylene blue to 80 c.c. (℥ iiss.) serum.

June 7th: The fluid is receding.

June 12th: Discharged cured.

Case XX.—J. A——, female, aged twenty-two years, admitted June 16, 1899. She has had a cough for three months, with pain on the left side. She is anæmic and weak. Diagnosis, effusion in left side.

June 20th: Injected gr. x. methylene blue to 80 c.c. (℥ iiss.) serum.

June 21st: Methylene blue shows in the urine.

July 10th: Discharged cured.

In the foregoing list, besides the injections of methylene blue as described, some cases received salicylates, some diuretics or cathartics, and others no internal medication at all. So far as I could determine, drugs used internally had little or no influence on the rapidity of absorption. "Wolff bottles," as recommended by Dr. Walter James for facilitating lung distention, were employed in all cases, and with good effect. The shortest interval between the injection of methylene blue and its appearance in the urine was four hours. In four cases paracentesis was performed, a few days after injection, without cutting short the period of convalescence. No considerable reaccumulation of fluid could be made out in these cases, but absorption of the rest of the effusion—for it is impossible, even if advisable, completely to empty the chest-cavity—dragged along at a snail's pace, so that the time from injection to discharge from the hospital was something more than two days over the non-aspirated cases.

To illustrate the influence of methylene blue in inducing fibrin formation and subsequent adhesion between the pleural surfaces, the following case may be cited.

M. A.——, aged twenty-eight years, admitted September 9, 1899. Diagnosis, empyema. The patient had been ill about six months, and gives the following data: On April, 1899, the chest was aspirated, and about one quart of fluid removed, which he says "resembled urine in clearness and color." In June he entered a hospital, and remained there about three months, during which period the chest was emptied three times, and a "milky" fluid aspirated on each occasion. On September 7th, a "whitish" fluid was withdrawn from the chest by a private physician, and he was referred to Columbus Hospital, where a large empyema was found, and successfully operated on by my colleague, Dr. Walsh, on September 15, 1899. Daily irrigations of a boric-acid solution were employed up to October 22d, when a solution of methylene blue (gr. x. to two quarts of water) was substituted for the boric acid. The cavity at this time had a capacity of fifteen ounces, and had not perceptibly diminished in size since the operation. About four ounces of pus were evacuated daily. The blue appeared in the urine on the evening after the first irrigation.

October 27th: The cavity holds twelve ounces, and the daily quantity of pus is much diminished.

October 30th: The cavity is irrigated every other day.

November 8th: Irrigated every third day with methylene blue solution (gr. v. to two quarts of water. The blue persists in the urine about forty-eight hours as a rule, when only faint traces can be detected.

November 15th: The cavity holds eight ounces. About two ounces of purulent fluid accumulates at each irrigation (every third day).

November 22d (one month after the employment of the blue). The cavity holds seven ounces; accumulation of pus for the past three days, one ounce. The patient has gained weight and strength. The chest has contracted one and one-half inches.

Besides the use of the methylene blue in the pleural sac, I have also employed it, in a similar way, a number of times in the peritoneum and twice in the tunica vaginalis. In the latter cases the blue promptly appeared in the urine, and the next day there was a marked diminution in the tension of the sac and amount of contained fluid. As these patients had entered the hospital for ailments other than hydrocele, the latter condition was not discovered by me until the patients were about to be discharged. They therefore left the hospital two or three days later, with instructions to return to the dispensary should the tunic refill. They never came back, however, and I have no knowledge of their subsequent history.

In the peritoneal cases the injections were more for the purpose of experimental observations than for curative effects. Ascites due to hepatic obstruction can, of course, be only temporarily alleviated by increased action of the absorbents. Here the cause of the transudation is constant. Ascites due to peritonitis, tuberculous or simple, however, presents a fertile field for experimentation, and I greatly regret my inability to report some cases in effusions of this character. That patients suffering from ascites secondary to hepatic cirrhosis may derive benefit from the injection of the blue aniline is shown by the following case (one of a number):

J. S——, aged twenty-seven years. Diagnosis, large ascitic effusion from cirrhosis of the liver. He has been ill two years. He was tapped three times prior to admission. He suffers great abdominal pain, and is compelled to remain in bed.

September 20th: Injected gr. xv. methylene blue to 100 c.c. (℥ iii. ℥ ii.) serum. The urine showed the dye three hours later.

September 21st: The abdominal pains are about gone. The amount of urine is increased. The patient got out of bed.

September 25th: The blue is absent from the urine. He has been walking about the ward, and feels better in every way. There is no pain, and but slight tenderness over the abdomen.

September 27th: The abdomen was tapped, and one hundred and sixty ounces of a slightly turbid serum was removed; reaction, neutral; specific gravity, 1.017, with faint traces of methylene blue. Discharged improved.

In this, as in every other case in which I have used the dye, no pain followed; and if pain was present prior to the injection, it (the pain) was diminished, rather than increased. As a rule, there was no rise of temperature. Lemoyne[1] recognizes the analgesic properties of methylene blue in migraine, sciatica, rheumatism, and the abdominal pains of tabes, and his views have been supported by many other observers.

In general, it may be said that the injection is attended with no more pain than the ordinary aspiration, and takes less time. The patient usually walks to the treatment room, and returns to his bed or the ward according to his own inclination.

The belief that serous effusions, of the pleura at least, are due to the irritation of bacteria or their toxins is constantly gaining ground, so also is the impression that among these germs the tubercle bacillus plays a leading rôle. Notwithstanding the fact that the tubercle bacillus has been only exceptionally found in serous effusions, injection experiments and culture methods, together with the subsequent history of the cases themselves, strengthen the opinion that the process, in a vast majority of cases, is primarily tuberculous.

[1] Bulletin général de Thérapeutique, April 15, 1899.

Pansini[1] reports, out of fifteen cases of sero-fibrinous pleural effusion, six with tubercle bacillus, three with diplococcus pneumoniæ, one streptococcus, and five negative. Netter,[2] on a basis of thirty-seven sero-fibrinous effusions, concludes that when no germ is found, the presence of the tubercle bacillus may be presumed. Jakouski[3] arrives at the same conclusion.

That the introduction of methylene blue into the pleural cavity, even in the dilute solution employed, will be inhibitory or fatal to the tubercle bacillus, as well as other germs, seems a fair inference to draw. Its antiseptic properties, although weak, are well established, and forming, as it does, a perfect solution with the serum, no part of membrane or effusion escapes its influence.

Case IX., as well as others, was without doubt a tuberculous effusion. The antecedent history, the general symptomatology and appearance all pointed toward a tuberculous infection, possibly pulmonary, although repeated examinations failed to disclose the bacilli in the sputum. I saw this patient over a year after his discharge from the hospital, and found no return of the effusion. He was working at his trade, that of a shoemaker, had gained flesh, and was generally in a good physical condition.

The duration of treatment in serous effusions of the pleura, for obvious reasons, varies within wide limits. Glaeser,[4] in a most exhaustive article, on a basis of one hundred and seven cases cured by internal medication, gives the average duration of treatment as 56.3 days. In the twenty cases here reported the average was 13.1 days.

47 West Fifty-eighth Street.

## CONSIDERATIONS UPON THE PROPHYLAXIS OF GLANDERS IN HAVANA.[5]

By ENRIQUE ACOSTA, M.D.,

AND

J. N. DAVALOS, M.D.,

HAVANA, CUBA.

The case of glanders just reported by Dr. G. Lopez, and another one that we have been enabled to diagnose within a few days, compel us to submit to this learned body some considerations regarding this disease, which since 1888 has attracted so much public attention.

We shall not attempt even to outline a history of what has taken place here in reference to this malady, but we must state that for many years we have struggled faithfully in strenuous efforts to cause its disappearance: in company with Dr. Juan Santos Fernandez we formed part of ridiculous "official" committees in endeavors to obtain its extinction; we saw a fellow-worker succumb to the infection, Dr. Diaz; we suffered bitter and undeserved censure; our scientific capacity was questioned, and we witnessed the death of numerous individuals; we obtained nothing, because all our efforts were powerless against the influence of those who, commanding great wealth, overcome all difficulties by bribing the veterinarian, the ward deputy-mayor, or even the governor himself. By this easy means, stable owners made free use of infected animals, exposing them in the public streets so that two or three deaths from glanders were reported every month.

When, after corroborative bacteriological evidence, a horse was reported suffering from the disease, if a newly arrived and unscrupulous veterinarian was consulted, three things were sure to result: (1) a healthy horse was temporarily substituted; (2) the animal was declared not infected; (3) the veterinarian became an employee of the stable where the horse belonged. Thus, many years went on, until last January, when the new condition of things led us to hope for improvement. In fact, the American government has placed the work of looking after this disease in very able hands.

We know the good work realized by the inspector, and for that very reason, having learned of the recent cases in the human subject, we wish to point out the real agents which maintain glanders among us.

When, a few months ago, we had the honor to read before you our article upon anthrax, we knew not whom to blame for its continuous occurrence. The municipal corporation defended itself, alleging that the American authorities curtailed its rights, and the latter asserted that their supervision did not extend to the slaughter-house, corrals, etc.

In bringing the question of glanders before you, we expect to meet with similar difficulties, for we see that the sanitary department has charge of the hygiene of stables, etc., while the municipal corporation issues ordinances in the same direction. At all events we shall comply with a scientific duty in stating our opinion regarding the present means of prophylaxis employed against glanders, and the Academy will deliberate and act in accord with its high prestige and scientific representation.

Glanders, as you know, is an infectious disease peculiar to an animal species, and is transmitted by direct or indirect contact to man. In all civilized countries where it exists, prophylactic measures are directed to obtain its extinction, and the disease is much under control. Only in the island of Cuba has the infection remained firmly rooted, to the extent of causing from twenty to thirty deaths per year.

The prophylactic measures at present employed may be divided into three factors: (1) one inspector who examines the horses, (2) a so-called hospital, and (3) a very good set of municipal ordinances on the subject. The inspector, gentlemen, does more than could be expected of any one. He is well informed, honest, and energetic, unbending before threat or bribery; he carries on an actual prosecution against glanders; he is well acquainted with all infected spots and has compelled the sacrifice of numerous diseased animals. But his authority does not reach beyond a certain limit, and this has rendered some of his work most unfortunately fruitless. Not many days ago, having found numerous infected animals in two stables, he ordered them taken to the hospital and the stables to be closed; we know not what happened after that, but the stables were neither closed nor disinfected, and it was attempted to compel him to revoke the order. There have been several instances like the above which have forcibly reminded us of the Spanish régime, but with the notable difference that at that time every one allowed himself to be bribed by friendship, influence, or money, while to-day the inspector alone resists temptation.

As to the so-called hospital or lazaretto, when you become acquainted with it you will understand why we name it so. It occupies a small area of land situated in one of the corrals belonging to the old School of Agriculture, in the neighborhood of Cienaga. It is composed of a broken tile roof supported by posts; there is only one lateral wall, made of old timber and extending only part of the distance. There are two small rooms inside of the square, occupied by the family of the keeper. The mangers have no way of keeping the horses separated. The ground is mostly

[5] Read before the Havana Academy of Medicine in November, 1899.

mud, which is stirred up into a thin slime when it rains through the roof. This is the hospital to which infected or suspected horses are taken. Nothing more loathsome can be conceived of, and nothing more favorable to the propagation of glanders than this spot destined for the observation of suspected animals. More than forty sick and suspected horses often congregate in this filthy corral; many are killed, some are returned infected, and others finally die of the disease.

What is done with their dead bodies? Those that die at the hospital are buried in the neighborhood, while those that have the strength to reach Chorrera (a suburb) are killed there and the remains utilized. The skin, fat, bones, etc., are sold, and no one stops such dangerous and criminal commerce. When we visited this so-called hospital and spoke to the inspector about its condition, he told us that he could do nothing; that he was tired of presenting complaint and protests. He said that in his opinion the hospital was the greatest focus of glanders infection.

We left the hospital profoundly disappointed; our hopes of last January had come to naught. The contagion, in this way disseminated over cities and towns, protected by an unknown and invincible hand, will continue to claim its regular quota of human victims.

The third factor, the set of municipal ordinances, is above criticism. It embraces all that is required for the prevention of glanders: inspection of public and private stables; inspection of all corrals and pastures; the use of mallein for the purposes of diagnosis; and lastly the establishment of a modern lazaretto. But in spite of their publication in the *Official Gazette*, and presumably their thus having gone into effect, the regulations above mentioned remain as so much dead letter.

We have again to think of the confusion of authority that we see all around us, and which is so detrimental to our public and private hygiene.

In fact, gentlemen, the inspection of stables and corrals is in the hands of the American sanitary department when it ought to be under the control of the municipal corporation, which, to judge by its ordinances, is quite competent to undertake the work of forever extinguishing this dreaded infection. It is time that the municipal authorities take the matter in hand, since, as the work is performed to-day, we find cause only for censure and protest. If they do not discharge the obligation which they assumed by the issuing of their ordinances, we shall continue to cry against the causes which at all times have made of glanders a source of moral imposition and material extortion.

From the above it is evident that we can draw but one conclusion: that the prophylaxis of glanders, as carried out by the present authorities, is a menace to public health, and that it ought to be placed in the hands of the municipal corporation, which offers better means for its realization.

---

**Rigors in Disease.**—You will not have failed to note how frequently the occurrence of a rigor in a medical case at once determines the need for surgical interference, and how prompt we are to avail ourselves of it. In the treatment of a patient suffering from a rigor you are to employ warm drinks such as hot tea with essence of ginger, and apply extra blankets and hot bottles. Some ether or carbonate of ammonium may be given, or brandy and hot water. If the pinched and collapsed condition lingers, a tablet or two of trinitrin may be given sometimes with advantage. The exciting cause may, however, be diligently sought for and treated as far as possible.—Sir Dyce Duckworth (London *Lancet*, November 25th)

# Clinical Department.

## A CASE OF SUBCUTANEOUS CRANIOTOMY.

By SIDNEY F. WILCOX, M.D.,
NEW YORK.

The above title applies to a new operation which I have lately performed, and which I believe can be done only with the Gigli saw, or some modification of that instrument. The Gigli saw is described by Dr. W. W. Keen as "a bit of roughened steel wire about 35 cm. long and 0.5 mm. or more in diameter, with a loop at each end. The method of using the saw is to make two or more trephine openings, separate the dura from the skull, . . . draw the saw under the bridge, . . . attach a handle to each end of the saw, and cut outward." The principle of this instrument is the same as that of the old-fashioned chain saw, but being so much lighter, thinner, and stiffer, with no liability to kink or clog, it is a much better and more adaptable instrument. The operation which I wish to describe in this short article was suggested to my mind on seeing the Gigli saw used in a trephining case; and having occasion to operate on a patient the following week, I put the idea into practice. The case was one of a girl fourteen years of age, well grown and developed physically, but very backward mentally. She had a dull, sleepy look with half-closed eyes, and her mental non-development was manifested by her imperfect speech, her limited acquirements, and some muscular inco-ordination. Her mother, an unusually bright woman, states that, in spite of the child's sleepy look, she had never seen her asleep; and an examination of the skull with the *x*-ray machine indicated unusual thickness of the bone for a child of that age. It was thought by the neurologists who were consulted that undue pressure was being made upon the brain by the over-thick skull, or at least that expansion and development of the organ were inhibited, and the operation was undertaken with the object of relieving the pressure, and giving an opportunity for the brain to expand. Of course, it was largely an experiment, but I think the results thus far justify it. The operation was performed on February 7th of this year. Without going much into details, I will state that the whole operation consisted in first removing quite a large plate of bone from over the fissure of Rolando with the chisel, and then loosening up another large plate without cutting the scalp along the line of section through the bone. The latter portion of the operation was accomplished by first making two very small openings through the scalp and skull at some distance from the place where the plate of bone had been removed: then the dural separator was passed from one trephined opening to the other, and the saw pushed along its groove under the bridge of bone; the handles were attached and the wire was held out as straight as possible as the bone was cut through. As soon as this was done, the saw was pulled out without cutting the bridge of soft tissues. The instrument was then re-introduced so as to make the new line of section join the opening left by the removal of the original plate of bone. Thus an irregular quadrilateral piece of bone was loosened up, and the expansion of the brain promptly pushed it from within outward. In order not to produce a condition which could be similar to a depressed fracture, I drew the saw sidewise as it cut through the bone, thus bevelling the edges, so that, when pressure was made externally, the raised piece could only be pressed down into its original position. In other words, the portion of skull which was loosened might be likened to a stove lid, which fitted into the bevelled edges of the opening. Only a few weeks have elapsed since

the operation was performed, but the effect thus far has been good; although, of course, no judgment can be formed as to the permanent result in so short a period. The child now opens her eyes wide; the sleepy look is gone, and she sleeps naturally. She left the hospital two weeks after the operation, and I saw her about two weeks after that.

The points I wish to make are these: With the Gigli saw a piece or several pieces of bone may be loosened without cutting the scalp except to make very small openings sufficient to admit of placing the trephine on the skull. The attachments of the skull to the scalp and dura are not torn off, and there can hardly be a limit to the amount of bone loosened; and finally with aseptic precautions the operation is almost entirely free from danger. As to the results which may be accomplished, no one can tell as yet, but it seems to me that a new field may be opened up to the neurologist through the invention of this simple instrument.

51 West Fifty-second Street.

## JEQUIRITY IN THE TREATMENT OF TRACHOMA.

By R. H. T. MANN, M.D.,

Texarkana, Ark.

In well-selected cases the jequirity treatment of trachoma is far the best, and there are many cases which yield to this treatment when all other methods fail. This treatment is especially adapted to cases of long standing and when much pannus exists. Ten beans are finely pulverized and placed in a bottle containing one-half ounce of water. This solution is allowed to stand for twenty-four hours. A few drops of the solution are instilled into each eye once a day until a false membrane appears, which will be in most cases after the third instillation. Within two hours after each instillation pain sets in, and remains severe for six hours.

This treatment is followed by the daily application of a two-per-cent. solution of nitrate of silver, which is kept up until the eyes are well: this will usually be in from two to six months. I have used this method successfully in my practice in many cases, and have seen it used in many more, and have yet to see a case in which it has had any bad results; however, it might be advisable to use it in one eye at a time. The solution should be freshly prepared for each case.

I give here two cases which will serve to illustrate the treatment I have just outlined:

Case I.—A girl of twenty years had been suffering from trachoma for seventeen years. Vision was reduced to $\frac{1}{200}$ in each eye. She had consulted many physicians without relief. This patient was well in six months. Vision with properly adjusted glasses, $\frac{20}{60}$ in each eye. I saw her a short time ago, and she has had no recurrence of the trouble.

Case II.—A girl of fifteen years had been suffering from trachoma for four and a half years. The vision was reduced to simple perception of light in each eye. Pannus covered the upper half of each cornea. At the end of eight months she had made a complete recovery. Vision $\frac{20}{30}$ in each eye without glasses. I last heard from her one year and a half after I dismissed her. She had then had no further trouble.

**Nitroglycerin** is serviceable only in diseases connected with actual or relative spasm of unstriped muscular fibre. In pneumonia and other respiratory diseases there seems to be no rational basis for its use. —Marshall, *Lancet*, November 4th.

## Therapeutic Hints.

**Chronic Bronchitis.—**

℞ Acidi carbolici ..... 0.5
Ichthyol ..... 5.0
Spiritus vini ..... 10.0
Aquæ destill ..... 100.0
M. S. Inhale.

—Neusser.

**Pediculosis Capitis.—**

℞ Naphthol ..... 5.0
Olei olivarum ..... 100.0
M. S. Apply.

**Pyrosis.—**

℞ Sodii bicarbon.,
Pulv. rad. rhei .....āā 1.5
Sacch. alb ..... 3.0
M. div. in pulv. No. x. S. One t.i.d.

—Nothnagel.

**Chronic Constipation.—**

℞ Extr. aloes,
Extr. rhei,
Pulv. rad. rhei .....āā 2.0
Extr. colocynth ..... 0.3
M. ft. pil. No. lx. Sig. Three pills before retiring.

—Nothnagel.

**Hyperemesis Gravidarum.—**

℞ Morphinæ hydrochl ..... 0.2
Acidi acetici glacial .....q.s. ad sol.
Chloroformi ..... 5.0
Alcohol. absol ..... 15.0
M. S. Five drops in sugar water.

Or:

℞ Cocain. hydrochl ..... 0.25
Sacch. alb ..... 3.0
M. ft. pulv. No. x. Sig. One powder t.i.d.

—Schauta.

**Bronchitis.—**

℞ Extr. belladonnæ ..... 0.1
Extr. hyoscyami ..... 0.2
Pulv. pummosi ..... 3.0
M. ft. chart. No. x. Sig. One t.i.d.

℞ Pulv. ipecacuanhæ et opii ..... 2.0
Sodii bicarbonatis ..... 4.0
M. ft. chart. No. x. Sig. One t.i.d.

—Neusser.

**Pertussis.—**

℞ Pulv. rad. belladonnæ ..... 0.1
Sodii bicarbon ..... 0.4
Sacch. alb ..... 2.0
M. ft. chart. No. x. S. One powder q. 3 h.

—Widerhofer.

**Hydrocephalus.—**

℞ Sodii iodidi ..... 2.0–4.0
Aquæ destill ..... 90.0
Tinct. valerian ..... gtt. xx.
Syr. simplicis ..... 10.0
M. S. Tablespoonful every two hours.

—Monti.

**Pernio.—**

℞ Acidi nitrici puri ..... 3.0
Aquæ destill ..... 60.0
M. S. Apply locally.

—Gussenbauer.

**Hysteria.—**

℞ Camphor. monobromat.,
Extr. valerian .....āā 3.0
M. ft. pil. No. xxx. Obduc. fol. argent. Sig. One pill t.i.d.

—Krafft-Ebing.

**Peritonsillitis.**—If seen within twenty-four hours of the onset it can be aborted. The remedy thus efficacious consists of:

℞ Morph. sulph. ..... 0.06
Tinct. veratr. virid ..... 4.0
Aquæ ..... 120.0
M. S. Teaspoonful every hour for three hours; then once in three hours.

—Emil Mayer.

MEDICAL RECORD:

*A Weekly Journal of Medicine and Surgery.*

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, December 30, 1899.

## PROPOSED LEGISLATION FOR THE MEDICAL DEPARTMENT OF THE UNITED STATES ARMY.

THE surgeon-general of the army will present to Congress at the present session three bills relating to the medical department of the army. These bills cover three greatly needed reforms. They provide, first, for an increase in the medical department of the army; second, regulations relative to the efficiency of the department; and third, bills for the relief of acting assistant surgeons and assistant surgeons with the rank of captain in the volunteer service. The necessity for an increase in the number of regular medical officers has been apparent to the head of the medical department for some time, and it has been repeatedly brought before the attention of the legislative and executive branches of the government. The medical corps of the army at present consists of one hundred and ninety-two commissioned medical officers, while from the requirements of the service there are at present, in addition to these, over four hundred civilian physicians serving under contract as acting assistant surgeons. The number of medical officers belonging to the medical department was barely sufficient for the needs of the service during its hand-to-mouth existence prior to the war with Spain. The army then numbered twenty-five thousand men, and the medical officers, though all trained and expert in the performance of their duties, were hardly able by strict economy of working material to carry out the multifarious duties demanded of the medical department. Upon the outbreak of the war the medical corps had to be reinforced by a large number of physicians taken from civil life. In some cases these physicians had received preliminary training in military matters through association with the National Guard, but the large majority were without any training whatever. As a result of the influx of new men unacquainted with the special and peculiar duties which were required of them, and from the fact that the medical department of the army was so small in numbers as to be insufficient even to form the nucleus about which the untrained men could assemble for instruction until such time as they were able to work for themselves, more or less confusion, which is now a matter of history, resulted.

The duties of a medical officer of the army are such that he is in reality a specialist. It is not alone that he must be able to prescribe for the sick or operate upon the wounded, but he must exercise executive and sanitary functions. In time of peace he must not only be a practising physician and surgeon, but he is required to be the health officer of the particular post at which he may be stationed, and in addition to this he is required to exercise executive functions in the hospital over which he may have command. In time of war his field of activity both in executive and sanitary measures is greatly increased and proceeds along special lines. The sanitary and hygienic questions which arise relative to the care of men in camp and field are relegated to him. The questions of camp and field sanitation and hygiene offer problems markedly different from those of hygiene and sanitation in settled communities, and special training is required in this direction.

The modern army is a collection of highly specialized units which requires for its efficiency that all its component parts shall work harmoniously toward the end of its efficiency as a fighting force. Not only must the sick and wounded be treated, but care must be taken that sickness is reduced to a minimum and that all the precautions which are requisite to the health of an army should be known and practised by the military surgeon. It is here that the civil practitioner suddenly brought into the military service most frequently fails. The conditions which obtain in this country are such that dependence cannot be placed entirely upon a standing army of sufficient size to meet all possible emergencies, and the formation of volunteer forces at certain times of need is and will continue to be a settled policy of the government. This being the case, the established medical department of the regular army should contain a sufficient number of men to form a suitable nucleus about which the medical officers of the volunteer army may be organized and by which they may be instructed in times of war. With the medical department of its present size it will be overwhelmed at any time in the future when conditions similar to those which obtained at the outbreak of the war with Spain occurred.

But not only is an increased number of medical officers required to serve as a nucleus, but an increased number is required for the needs of the service as they actually exist at the present time. As a result of the increase in seaboard defence eighteen new posts have been established upon the seacoast in the Department of the East, and ten have been established in the Department of the Columbia, including Alaska. There are now eleven independent garrisons in Porto Rico and a large number of independent commands in Cuba and the Philippines. These independent garrisons and commands all require medical officers of experience and ability, and in addition all the higher executive offices of the medical department have to be filled with men of a rank commensurate with the positions which they occupy. It is absolutely impossible to do this with the present number of medical officers, hence the request of the surgeon-general for legislation as to an increase of the corps.

Relative to the increased efficiency of the medical corps, this will be obtained not only by an increase in number of the medical department, but by the proposed legislation for a period of probation for all medical officers of the regular establishment. The bill provides that all candidates who have passed the medical examining-board in compliance with existing regulations shall be appointed acting assistant surgeons for a probationary period of six months. During this probationary period they will attend the Army Medical School, established in the city of Washington and at the end of the probationary period the faculty of the school will report to the Secretary of War upon the fitness and relative standing of the probationary candidates. This measure is to the end that more careful selection of men may be made relative to their adaptability to the medical service than can be done as at present by a single, comparatively brief examination.

The bill for the relief of acting assistant surgeons provides, first, for the granting of leaves of absence to acting assistant surgeons, as is now provided for all commissioned officers of the army, and also that their pay shall be continued during absence from duty on account of sickness contracted in the service. The justice of this legislation is so manifest that it hardly requires comment. It is manifestly unjust that surgeons serving under contract in the army should be deprived of all rights and privileges regarding leaves of absence, and should have their pay stopped when they are absent from duty by sickness contracted in the service. No other class of men in the military service are so discriminated against, and it is but a matter of common justice that these discriminations should be done away with.

The bill for the relief of assistant surgeons with the rank of captain provides that assistant surgeons in the volunteer army commissioned as captains shall be entitled to the pay of "captain, mounted." At present the assistant surgeons of the volunteer army of this rank are allowed the pay of first lieutenants only, the decision being that the act of Congress providing that assistant surgeons shall receive the pay of captain only after five years of service holds in these cases. As all other captains of the volunteer army receive the pay of captain, it is a discrimination against the assistant surgeons of this rank which should be corrected by proper legislation.

It is to the interest of the medical profession at large throughout the country that the legislation above referred to be enacted. The members of the medical corps of the army are graduated from the same schools as are the members of the profession at large. All of the principal medical colleges are represented in the ranks of the medical corps. The efficiency or non-efficiency and the method of performance of the duties imposed upon them reflects, therefore, not only upon themselves, but upon the profession at large, and it therefore becomes the duty of the profession to further in every way legislation which may increase the efficiency of this representative body. It is not too much to ask that personally and collectively, both as individuals and as medical societies, the medical profession of the country present to their representatives in Congress the urgent necessity for the proposed legislation.

## FEEDING AN ARMY.

To feed an army in the field at a very considerable distance from home is no light task, and upon its successful accomplishment hangs much of the ultimate issue of a campaign. It would seem at first sight as if the Boers should decidedly be in a more favorable position as regards this aspect of the situation than the British. Undoubtedly, however, such is not the case, and this fact can be easily explained when the subject is more carefully looked into. The Transvaal and Orange Free State must both be self-supporting during the war, as, the British having command of the sea, they will be unable to import provisions into the country, and the time will come, and is probably now not far away, when their own supply will fail. *The London Hospital*, quoting from the London *Times* of November 30th, tells that the provisioning of the British army rests upon the principle of maintaining a four months' supply of food at the base of operations; and that, therefore, when this supply is established it must still be replenished at short intervals and to a sufficient extent to keep pace with the daily rate of consumption. There have to be maintained in South Africa, roughly speaking, one hundred and sixteen thousand men, including soldiers and those engaged in the work of transport, and fifty-one thousand horses and mules. At the present time there are supplies for only three months in the country, but the necessary additions are being rapidly and continuously despatched, so that the theoretical standard of quantity will soon be attained. What these quantities are can be stated only in figures which, like those expressive of astronomical distances, practically elude the imagination. Among the chief items are twelve million pounds of preserved meat, and an equal quantity of biscuits. At an approximate computation the preserved meat alone would occupy a space about equal to that of a terrace of ten houses, each house thirty feet high, thirty feet deep, and with a frontage of thirty feet. Then come four hundred thousand pounds of coffee, two hundred thousand pounds of tea, two million two hundred thousand pounds of sugar, eight hundred thousand pounds of compressed vegetables, four hundred thousand pounds of salt, and one million five hundred thousand pounds of jam, as essential requirements of the military storeroom. Sugar is now universally admitted to be an admirably nutritious article of diet, and the jam affords in combination with sugar vegetable elements which are of high importance for the prevention of scurvy. A further provision in this direction is that of four hundred thousand pounds of lime-juice, while other needs in the way of liquids are met by eighty thousand gallons of rum, twelve thousand bottles of whiskey, thirty-two bottles of port wine, a "vast quantity" of sparklets for making soda water, and eighty tons of alum for purifying spring or river water the quality of which

may be doubtful. In addition to all this there are the forage for animals, and the supply of not only these animals themselves, but also of the wagons to which they are to be harnessed, and of the harness itself which are to be considered. The first idea was to obtain wagons and mule harness in large quantities from the United States, but it was considered that they approached too nearly to "munitions of war" for this course to be pursued, and the demands are in the way of being fully met by the unaided resources of the empire.

Of course canned meat must be largely used in a country where the supply of cattle on the hoof is not equal to the demand, but the aforesaid meat should be rigorously inspected ere it is dispatched to its destination. Now, too, that many more British and colonial troops are to be poured into South Africa, the War Office will doubtless have to strain every nerve in order to transport provisions sufficient to maintain the supply at the base of operations at the standard of four months.

## THE APPENDICITIS QUESTION AGAIN.

"To operate, or not to operate, in appendicitis" is still one of the absorbing questions of the hour. The physician proper still leans favorably to the expectant plan of treatment, while the operator urges removal of the appendix in all cases as being the only method of cure. The surgeon, however, weighs the pros and cons for operation in each case, and governs his action accordingly. Of course each patient, and every attack of appendicitis, must be considered as an entity, and no steadfast rules can be set down to govern all cases. Certain clinical facts have been demonstrated so often in the course of this affection that broad lines of action may be formulated upon them. Briefly stated these are as follows:

1. As we can never tell from the nature of a previous attack of appendicitis what will be the character of the next seizure, or when, if ever, it will occur, a patient who has had one mild attack should have this clinical observation clearly stated to him, and the decision for or against operation left with him. If a patient has had more than one attack, the probability of a recurrence is much stronger, and the surgeon may even urge an operation in the interval, the burden of responsibility, in case of refusal, being placed upon the shoulders of the patient. Under this head belong all those cases in which, after the subsidence of the acute seizure, the parts apparently return to their normal condition. Should adhesions of the appendix to neighboring structures have occurred, which in themselves cause pain and interference with the general well-being of the individual, there would exist a further indication for surgical interference.

2. If, during the course of an acute inflammation of the appendix, there is manifested a distinct tendency to a regression, we may safely wait for the subsidence of the attack, and then consider the patient as outlined above. Such regression is determined by careful observation of the triad of symptoms, which in relative importance are: (*a*) Pulse rate; (*b*) local pain and rigidity of the abdominal muscles; (*c*) temperature elevation. If the pulse rate steadily declines and the other two symptoms become less marked, the inflammation is regressing, and operative attack can be deferred.

3. But if there is a distinct progression as indicated by an increasing rapidity of the pulse, and more marked local pain and rigidity, irrespective of temperature elevation, operation is urgently demanded.

4. Abscess cavities call for immediate careful evacuation.

5. General peritonitis demands immediate operative interference, except when the general condition of the patient forbids a formidable procedure. Such latter patients do better if treated expectantly, and often enough these desperate cases improve, and then their subsequent surgical treatment depends upon the local condition.

These general principles of action will be found to govern the vast majority of cases. But one must never forget that appendicitis does not always run a typical course, and in the atypical cases the internist and the surgeon both must rely on their past experiences to enable them to decide for or against operation.

## News of the Week.

**Possible Murder of a Medical Student.** — A young man named Hirth, a student at the College of Physicians and Surgeons, was found dead a few days ago on Woodlawn Heights with a bullet hole in his head. In his pocket was a box containing cartridges, but no pistol could be found. The shot had been fired at very close range, for the skin of the face was powder-burned.

**Mr. Dwight L. Moody,** who died last week, offered a gratifying contrast to many of his cloth, especially revivalists, in his appreciation of regular medicine and his antipathy to quacks. In speaking of a prominent Christian scientist, or faith healer, or what-not, in Chicago, whose offences against humanity and common sense are many and notorious, he praised medicine as the noblest of professions after that of the ministry. "Never yet," he said, "in all my years of work have I called upon an able doctor, telling him of the sickness and need of some poor friendless person, that he did not at once go to the rescue, without money and without price. Some of the noblest men I ever knew have gone out as medical missionaries, devoting their lives to doing good with the skill and healing medicines the Lord has conferred upon them." "These are the men," he continued, "who are called devils by the 'faith healers,'" but he prayed God to forgive those guilty of such slander. "God heals," he said, "through doctors and through medicines. Do not be carried away through ravings of fanaticism. We have a new 'ism' in America about every year—beware of the 'isms'! What would I do if I fell sick? Get the

best doctor in Chicago, trust to him, and trust to the Lord to work through him. The doctors have done wonders as their knowledge has grown; they have reduced the dangers of death from diseases that once slew all they touched; and the doctors, if God helps them, will yet find a way to stop the ravages of other terrors."

**Fire in the Colored Home.**—Fire occurred last Saturday in the laundry building of the Colored Home and Hospital in this city. The laundry building is distant about twenty feet from the main building where the wards are located. The patients, most of whom are helpless, were kept in ignorance of the fire, and the latter was extinguished, after having caused about $2,500 damage, without being communicated to the main building.

**Rabies in Washington.**—There is a rumor in Washington that a mad dog has been running amuck through the city, and war has been declared on all canines. An order has been issued that all dogs must be muzzled, and all unmuzzled animals are taken to the pound and killed, unless claimed within a definite time. Nearly five hundred dogs were apprehended in one week.

**Navy Department,** Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending December 23, 1899. December 18th.—Passed Assistant Surgeon W. M. Wheeler detached from duty at the naval hospital, New York, and ordered to the *Vermont*. Assistant Surgeon H. A. Dunn detached from Port Royal naval station on reporting of relief, and ordered home, and to wait orders. Assistant Surgeon M. S. Elliott detached from the *Vermont* on reporting of relief, and ordered to duty at the Port Royal naval station. Assistant Surgeon E. Davis ordered to duty at the naval hospital, New York. Assistant Surgeon W. L. Bell detached from the *Independence*, December 31st, and ordered to the island of Guam on the *Scindia*. December 20th.—Surgeon H. T. Percy ordered to the Norfolk navy yard, January 4th. Surgeon H. E. Ames detached from the Norfolk navy yard on reporting of relief, and directed to proceed home and to be ready for orders to sea service. December 21st (Changes by cable from the Asiatic station).—Medical Inspector R. C. Persons detached from the *Baltimore* and ordered to the *Brooklyn*. Medical Inspector G. E. H. Harmon detached from the *Brooklyn* and ordered to the *Baltimore*. Surgeon O. D. Norton detached from the *Solace* and ordered to the *Monadnock*. Passed Assistant Surgeon C. H. T. Lowndes detached from the *Princeton* and ordered home. Passed Assistant Surgeon J. Stoughton detached from the *Monadnock* and ordered to the *Bennington* via the *Solace*. Assistant Surgeon C. D. Langhorne detached from the *Monterey* and ordered to the *Princeton*.

**Memorial to the Late Dr. William Pepper.**—In connection with the formal opening of the Free Museum of Science and Art, and its transfer to the trustees of the University of Pennsylvania, on December 20th a statue of the late William Pepper was unveiled, and his widow made a memorial gift of $50,000 for carrying on the work. The building cost $385,000, while the ground on which it stands is worth $225,000.

**The Late Dr. Charles Inslee Pardee.**—At a regular meeting of the board of directors of the Manhattan Eye and Ear Hospital, held on November 21st, the chairman, George E. Sterry, vice-president, called the board's attention to the loss that the hospital has suffered in the death of Dr. Charles Inslee Pardee, and on motion appointed Dr. Roosa and Mr. George G. Moore a committee to draft suitable resolutions. Dr. Roosa remarked that he was a classmate in the medical college with the late Dr. Pardee, and that he had been intimately acquainted with him from that time until the time of his death. His death was very sudden, said to be from apoplexy. After graduation, Dr. Pardee served gallantly and efficiently as a medical officer in the volunteer service during the Civil War. On his return, he was associated with Dr. Roosa in the University Medical College, and, as his assistant, he was with the speaker on the opening of the Manhattan Eye and Ear Hospital, and served there as an assistant surgeon on the very first day that Dr. Roosa's clinic was opened for the reception of patients. He was elected surgeon in 1879, and continued his duties there until he was appointed dean of the medical faculty of the university. His labors in the medical college were so exacting that he was obliged to resign his position as surgeon of the Manhattan Eye and Ear Hospital. But he, on the nomination of the late Dr. Agnew, was made a director of the hospital, in which position he served with punctuality and faithfulness until his death. Dr. Pardee was an astute and skilful practitioner, and he was so successful as dean of the medical faculty, that the speaker has heard the late Chancellor Crosby say he was worthy to be made chancellor of the university. He was very genial and interesting in social life, and, as has been said by the chairman of our board, we all deplore his loss.

"The Board of Directors of the Manhattan Eye and Ear Hospital record with profound regret the death of their late colleague, Dr. Charles Inslee Pardee. Dr. Pardee was appointed assistant surgeon at the Manhattan Hospital in 1869, and promoted to the surgeonship in 1879. He resigned the latter position on the 17th of November, 1885, and was thereupon elected a director of the hospital, which position he continued to occupy until the day of his death. He died on the 3d of November, and the board of directors make this record of his services to the institution, which were always of a high order.

"It is directed by the board that a copy of this be sent to the family of the late Dr. Pardee, and to the medical journals."

John Sinclair, *President;* A. G. Agnew, *Secretary.*

"*Resolved*, That this board [of Manhattan State Hospital], having learned, from the report of the general superintendent, of the death of Prof. Charles Inslee Pardee, M.D., of the board of consulting physicians and surgeons of this hospital, place upon record its sense of the valuable services rendered by Professor Pardee to the hospital during his connection with its consulting board, dating from that board's

first organization in 1879; its sincere regret at their termination; and its sympathy for his family in their affliction.

"*Resolved*, That the secretary be requested to enter a minute of the board's action upon the records of the hospital, and to transmit a copy thereof to Professor Pardee's widow."

**The Late Dr. Samuel Ketch.**—The following resolutions were adopted at a meeting of the staff of the New York Orthopædic Dispensary and Hospital, on December 15, 1899:

"*Whereas*, It is with profound sorrow we have learned of the death of our late associate, Dr. Samuel Ketch; and

"*Whereas*, During his long service as a surgeon of the Orthopædic Dispensary his colleagues and fellow-practitioners have had abundant opportunity to testify to his many good qualities as a skilful orthopædic specialist, as a cultured scholar, an earnest teacher, and a genial friend—

"*Resolved*, That by the untimely removal of Dr. Ketch the staff has been deprived of one of its most valued counsellors, the institution has lost a faithful officer, and the medical profession mourns a brilliant speaker, a fluent writer, a courteous and dignified member.

"*Resolved*, That we give public expression of our high appreciation of the man as we intimately knew him, and that we furthermore extend to his afflicted relatives our heartfelt sympathy in their sad bereavement."

Committee, H. J. Bogardus, M.D., Russell A. Hibbs, M.D.

**Obituary Notes.**—Lieut.-Col. David L. Huntington, United States army, retired, died in Rome, Italy, on Wednesday. He was born in Charlestown, Mass., in 1834, and served for thirty-six years continuously in the medical corps of the army. He was a graduate in arts of Yale College, and in medicine of the University of Pennsylvania in the class of 1857. At the beginning of the Civil War he was appointed assistant surgeon in the regular army and assigned to various places in the West. Later he became medical officer on General Grant's staff. He was medical director of the Army of the Tennessee, and accompanied Sherman on the march from Atlanta to the sea. For some years prior to his retirement he was in charge of the Medical Museum in Washington, and edited "The Medical Record of the War." He was a delegate to the International Medical Convention held at Moscow, Russia, in 1897, and after his return to the United States he was placed on the retired list April 10, 1898. Since that time he had lived abroad.

Dr. Albert P. Walter died at his home in Jersey City on December 18th, after an illness of six weeks, from peritonitis resulting from typhoid fever. Dr. Walter was born in Easton, Pa., in 1853. He was a graduate of the College of Physicians and Surgeons, Baltimore, in 1884.

Dr. William D. Camp, of Millerton, N. Y., died in that place on December 21st, of disease of the heart. He was fifty-seven years old, and was a graduate of the medical department of the New York University in 1870. He had two brothers who are physicians, one in Connecticut and the other in Massachusetts.

Dr. Jesse C. Miller died suddenly at Marklesburg, Pa., on December 21st. He was graduated from Jefferson Medical College in 1884.

Dr. Edward Higginson Williams, a member of the firm of Burnham, Parry Williams & Co., proprietors of the Baldwin Locomotive Works, died at Santa Barbara, Cal., on December 21st, at the age of seventy-five years. He was graduated from the Vermont Medical College at Woodstock in 1846. During his early medical career he had successful charge of the famous case in which a three-foot tamping bar was blown through a man's head. He subsequently undertook the business of engineering, and he gradually advanced in his profession until in 1890 he became a partner in the Baldwin Locomotive Works.

Dr. William B. Canfield, of Baltimore, died in this city on December 26th, from a fracture of the skull received in a fall about a month ago. He was found unconscious on West Seventy-second Street and was carried to the Roosevelt Hospital, where he remained until he died. Dr. Canfield was forty-four years old, and was a graduate of the University of Maryland School of Medicine in the class of 1880. After graduation he studied in Europe for a year and then began practice in Baltimore. He was for several years editor of the *Maryland Medical Journal*.

Dr. Charles Herwisch died at Philadelphia, on December 14th, at the age of forty-seven years, as the result of injuries received in a runaway accident the day before. He was a native of Austria, and was a graduate of the medical department of the University of Pennsylvania. He was a physician to the Rush Hospital for consumptives and instructor in clinical medicine in the Philadelphia Polyclinic.

Dr. Frederick Z. Johnson died at Corona, N. Y., on December 12th, at the age of thirty-one years.

Dr. Jonathan M. Higgins died at Philadelphia on December 15th, at the age of fifty-eight years. He was graduated from the medical department of the University of Pennsylvania in 1861, and was for nineteen years a member of the nineteenth sectional school board.

Dr. Walter Boardman was found dead at his home at Lancaster, Pa., on December 16th. He was thirty-eight years old, and was connected with Battery C of Phœnixville, prior to the outbreak of the Spanish-American War.

Dr. Stephen T. Beale died at Philadelphia on December 12th, at the age of eighty-five years. He was born in England, but came to the United States at the age of seventeen. He was graduated from Jefferson Medical College in 1847, engaging in the practice of medicine and of dental surgery, but after a time relinquishing the former. He was one of the founders of the Pennsylvania Association of Dental Surgeons and its first vice-president. He was instrumental in securing a charter for the Philadelphia College of Dental Surgeons, from which in 1853 he received the honorary degree of Doctor of Dental Surgery.

# Reviews and Notices.

Essentials of Diseases of the Skin. By Henry W. Stelwagon, M.D., Ph.D., Clinical Professor of Dermatology in the Jefferson Medical College; Physician to the Department of the Skin, Howard Hospital; Dermatologist to the Philadelphia Hospital, etc. Fourth edition, thoroughly revised. Illustrated. Philadelphia: W. B. Saunders. 1899.

This arrangement of questions and answers, covering the field of cutaneous and syphilitic affections, has evidently met the requirements of a large number of students, as we predicted for the first edition. Some practitioners might like this manner of self-questioning, having the answers under the eye, but most will undoubtedly prefer a more continuous text. Teachers and quiz masters might use the work, which belongs to the series of Saunders' Question Compends, of which it is No. 11. The woodcuts are not good, and give often a very inadequate idea of the affection they are meant to represent.

A System of Medicine. By Many Writers. Edited by Thomas Clifford Allbutt, M.A., M.D., LL.D., F.R.C.P., F.R.S., F.L.S., F.S.A., Regius Professor of Physics in the University of Cambridge, Fellow of Gonville and Caius College. Vol. VIII. New York: The Macmillan Company. 1899.

The curious confusion in the numbering of volumes which has characterized this series appears again in this volume, which is called viii. on the title-page and vii. at the end of the index and also in the preface. In this volume the subject of diseases of the nervous system is continued and apparently concluded. The several sections are diffuse diseases of the spinal cord, limited diseases of the spinal cord, diseases of the brain, and "other diseases of the nervous system"—the last term including disorders of sleep, epilepsy, chorea, the tics, and other neuroses. There are twenty-nine contributors, among whom two—Drs. Andrew H. Smith and M. Allen Starr—are Americans. The list includes such well-known names as Bramwell, Bastian, Beevor, Ferrier, Gowers, Grainger Stewart, Risien Russell, and the editor. There are, in addition to thirty-four illustrations in the text, three plates, one of them representing the cord in a case of syringomyelia, drawn by Van Gieson.

Twentieth Century Practice. An International Encyclopedia of Modern Medical Science. By Leading Authorities of Europe and America. Edited by Thomas L. Stedman, M.D., New York City. In Twenty Volumes. Volume XVIII. Syphilis and Leprosy. New York: William Wood and Company. 1899.

Containing the fewest articles, this is still one of the most interesting volumes of the set. Two subjects are treated by three writers. Eduard Lang, of Vienna, presents a contribution upon "Acquired Syphilis"; Jonathan Hutchinson, of London, upon "Inherited Syphilis," and Prince A. Morrow, of New York, upon "Leprosy." These are subjects fraught with the greatest interest for all medical men at the present day. Volumes on end have been written upon all three topics, but we have here a review of what has actually been brought forth, in advancing our knowledge of these diseases during the past century. All three chapters show the master hand, and frequent passages show the facile pen. The faculty of making a strictly scientific article, and at the same time interesting reading, is not within the powers of all writers. At the end of Lang's article are twelve pages of formulæ, among which will be found many useful in the treatment by baths, injection, or inunction, and many prescriptions to meet the various complications as they arise. Hutchinson is a writer who seems so well qualified by long and varied experience in the matter of inherited syphilis that he can give the results of a lifetime of investigation in a brief space. This he has here done. In about twenty-five pages he covers the subject, not alone well but entertainingly. Morrow's monograph takes up over two hundred and seventy-five pages, including ten of bibliography. This article is illustrated. No very new nor startling facts are brought out, but for a clear and accurate statement of the present knowledge of the subject in all its bearings, it leaves nothing to be desired. After all has been said that can be said, we are left in much the position we were in decades ago. No one seems able to tell absolutely in what manner the disease is transmitted and spread. No one claims much for any drug or method of treatment. The bacillus has been found, to be sure, but the ravages of the disease go on increasing in some regions while they abate in others, without, as it would seem, a just regard being shown for the efforts of man. Still the line of scientific endeavor in the matter of prophylaxis seems clear, and the author has indicated it in an appropriate chapter, giving a conservative though fair and dispassionate résumé of opinion in the matter of government control and segregation.

Differential Diagnosis with Clinical Memoranda. By Fred. J. Smith, M.A., M.D. Oxon., F.R.C.P. Lond., Physician and Senior Pathologist to the London Hospital. New York: The Macmillan Company. 1899.

This work is entitled an "Introduction to the Outlines of the Principles of Differential Diagnosis," and an attempt has been made by analysis of clinical symptoms to lead up to the underlying principles which govern disease processes. There is an element of originality in the work, though the author disclaims any attempt to introduce new facts in his efforts to arrange old phenomena in such a manner as to show more clearly than is usually the case their fundamental meanings and relationships. The work is suggestive, and points out the way to get at facts rather than the mere facts themselves. The lines of thought which almost every page introduces would prove of great value to the advanced student and medical thinker, writer, or teacher; but for the student preparing for his degree, or for the busy practitioner, it will hardly find a useful place.

A Manual of Diseases of the Nose and Throat. By Cornelius Godfrey Coakley, A.M., M.D., Clinical Professor of Laryngology in the University and Bellevue Medical College, New York City. Illustrated with 92 engravings and two colored plates. Philadelphia: Lea Brothers & Co. 1899.

A book is to be judged by its title, and as the present one is a manual, we are not to look for all the detail which is expected in a more formal treatise. Suffice it to say that in the present volume the principles of rhinology and laryngology are set forth with sufficient detail to enable the practitioner to take it as his guide for actual clinical work. The writer has long enjoyed the reputation of a careful clinician, and his manual is the outcome of a vast amount of practical work conscientiously performed. Especial praise is to be given to the paragraphs upon differential diagnosis, which is, after all, the most important factor in the daily work of one who has had a certain amount of experience; for while many problems in this field of medicine are unsolved, the field itself is no longer new, and as soon as the exact condition to be treated can be positively made out, the proper therapeutic measures will at once suggest themselves. Similar commendation is deserved by that portion of the book devoted to therapeutics. Dr. Coakley does not bewilder the beginner with a multiplicity of plans to be followed, but clearly sets forth what has been in his own work most successful. In diphtheria, he advises the employment "in connection with antitoxin, of those remedies which were so valuable to us before antitoxin was discovered."

An Introduction to Dermatology. By Norman Walker, M.D., Fellow of the Royal College of Physicians of Edinburgh; Assistant Physician for Diseases of the Skin to the Royal Edinburgh Infirmary. New York: William Wood and Company. 1899.

This octavo of two hundred and forty-seven pages is well illustrated, containing a colored frontispiece and twenty-nine plates, and having thirty-four illustrations in the text. It is written in a concise, easy, and attractive style, and suggests class-room clinical instruction unburdened by lengthy descriptions or detail of special cases. Rare forms have been omitted, while both sides of controverted questions are clearly and at times pointedly stated. The author credits Allan Jamieson with much that he has "unconsciously absorbed" from his teachings, while claiming for his own the "new-fangled" ideas which appear in the book. The influence of the German school is apparent throughout, and Unna is largely quoted, as are most of the English dermatologists, while American authors, with the exception of Duhring, are

almost ignored—and, indeed, the latter receives less credit for his dermatitis herpetiformis than might have been expected. Histological changes form the base upon which the scheme of classification is constructed. The most logical classification is thought to be that followed by Unna, and this, somewhat modified, has been adopted, beginning with anomalies of sensation and terminating with those of pigmentation. The arrangement of certain affections in the classes in which we here find them is open to criticism in several instances. Under infectious inflammations—by far the largest class—we find seborrhœa included as well as eczema, which on page 77 the author characterizes as the "rubbish heap," and further along as "inflammation of the skin, of the cause or nature of which the observer is ignorant." Undoubtedly many affections have been classed as eczema which are gradually finding their way into more definite groups, but we can scarcely do away with the term until our knowledge has advanced much further. Considering the many good features of the work, and despite the fact that the illustrations fall far behind many recent American productions, Dr. Walker's book may be taken as a trustworthy, safe, and easily followed guide. Since, however, the entire field of dermatology is not covered, larger text-books must be consulted for rarer forms, for more extended accounts, and especially for an adequate knowledge of syphilitic affections and their treatment. A peculiar oversight in the index on page 245 makes McCall Anderson's name appear as Anderson McCall.

PRACTICE OF MEDICINE. By JAMES M. ANDREWS, Ph.D., LL.D., Professor of the Practice of Medicine and of Clinical Medicine in the Medico-Chirurgical College, Philadelphia, etc. Third edition, revised. Philadelphia: W. B. Saunders. 1899.

THIS illustrated text-book of almost thirteen hundred pages has been revised in part, especially the chapter on infectious diseases, while portions have been rewritten and amplified. A few new illustrations have been added. The general scope and arrangement remain the same as for the last edition. That the work has been favorably received is shown by this third edition being required in less than a year from the second. In its new form it deserves a continuation of popularity.

## Progress of Medical Science.

**On Tremors.**—Levy Dorn gives as a result of a series of comparative studies on cases of tremor of diseased conditions and mimicry tremors the following general physiological conclusions: The cerebral ganglia are able to give rise to just as many simultaneous impulses as can the subordinate centres. Thus should the assumption be made that the cortex is involved in the process giving rise to the tremor, the physiological facts derived from the study of mimicry tremors would substantiate it. That is, voluntary tremor can be made to correspond in rhythm and number with the known tremors of disease.—*Virchow's Archiv*, 155, p. 591, 1899.

**Hemorrhagic Nephritis and General Infection.**—Peter Holst (*Deutsche Medizinal-Zeitung*, November 13th) reports three cases of acute hemorrhagic nephritis which were manifestations of a more or less latent generalized infection. In one case there existed a generalized streptococcus infection (blood, liver, kidneys, spleen) which for eight months presented itself as a hemorrhagic nephritis, and which ran an afebrile course until the last few weeks of life. The second case, which was also an afebrile one, presented in addition to the hemorrhagic nephritis a fresh endocarditis (staphylococcus infection). The third case occurred in a patient suffering from disturbed compensation, from whose urine a pure culture of staphylococcus albus was cultivated. He concludes by saying that (1) hemorrhagic nephritis is often a manifestation of a blood infection, a latent pyæmia or septicopyæmia; (2) the transient hemorrhagic exacerbations during the course of a chronic nephritis are also perhaps traceable to a temporary infection of the blood.

**Post-Scarlatinal Nervous Affections.**—Moureyre (*Berliner klinische Wochenschrift*, November 6th) is credited with saying that the following nervous diseases may occur after scarlet fever: (1) Neuralgia or neuritis of the lower extremities and post-scarlatinal tabes; (2) encephalitis and myelitis, as well as laryngeal stenosis due to nervous paralysis; (3) neuroses, such as hysteria and chorea; (4) psychoses.

**The Bacteriology of Impetigo.**—In the conclusions of Marié Davy's contribution to the study of the bacteriology of impetigo we find that the micro-organism of the affection is a streptococcus having short chains; that this streptococcus is the only agent of infection, and that there is no microbic association; that staphylococci are encountered in impetigo only as accidental inactive elements, or as the result of lesions accidentally engrafted upon the original process but quite distinct. The author does not seem to have determined whether this streptococcus is specific to impetigo.—*Annales de Dermat. et de Syph.*, October.

**Gastro-Intestinal Acquired Syphilis.**—In opposition to the views upheld by Neumann and Dieulafoy that acquired syphilis of the gastro-intestinal tract does not occur, Fraenkel reports such a case in which an autopsy was obtained (*Virchow's Archiv*, 155, p. 567, 1899). The clinical history was one of gastro-intestinal inflammation, and death resulted from perforative peritonitis. At the post-mortem examination there were found a great number of large and small ulcers scattered over the walls of the stomach, which showed the characteristics of syphilitic ulcers. There were, moreover, other ulcers of the small intestine, chiefly at its upper portion, numbering between thirty and forty. Some of these were circinate and others extended in patches almost around the entire circumference of the intestinal wall. Microscopical examination of the ulcers confirmed the macroscopic diagnosis. Thus their syphilitic nature could admit of no doubt. Small miliary gummata were also found in the arterial system, and there was in addition a gumma of the spleen which measured at least three inches in diameter.

**Urine in Disease.**—Dr. Formad (*Maryland Medical Journal*, September) concludes: 1. Sediment in the urine has no significance unless deposited within twenty-four hours. 2. Albumin in the urine does not indicate kidney disease unless accompanied by tube casts. The most fatal form of Bright's disease—contracted kidney—has little or no albumin. 3. Every white crystal in urine, regardless of shape, is a phosphate, except the oxalate of lime crystal, which has its own peculiar form; urine, alkaline. 4. Every yellow crystal is uric acid if the urine is acid, or a urate if the urine is alkaline. 5. Mucous casts, pus, and epithelium signify disease of the bladder (cystitis) or other parts of the urinary tract, as determined by variety of epithelium. 6. The urine from females can often be differentiated from the urine of males by finding in it the tessellated epithelium of the vagina. 7. Hyaline casts (narrow), blood and epithelial casts signify acute catarrhal nephritis. There is much albumin in this condition. 8. Broad hyaline casts and epithelial dark-green granules and oil casts signify chronic catarrhal nephritis. At first, albumin is present; later, less. 9. Hyaline and pale granular casts, and little or no albumin, signify interstitial nephritis. 10. Broad casts are worse than narrow casts, for the former signify a chronic disease. 11. The urine should be fresh for microscopical examination, as the micrococci will change hyaline casts into granular casts or

devour them entirely in a short time. 12. Uric acid may, in Trommer's test for sugar, form a peroxide of copper, this often misleading the examiner into the belief that he has discovered sugar. Thus, when urine shows only sugar, other methods of examination must be used, preferably the lead test. 13. The microscope gives us better ideas of the exact condition of affairs in examination of urine than the various chemical tests.

**The Uterus of Infants.**—As a result of careful and minute research, von Mandach, of Bern, contributes (*Virchow's Archiv*, 156, p. 94, 1899) some interesting facts with reference to the persistence of the Wolffian tracts in infants. The investigations were followed out by means of serial sections on eighty uteri in infants and children up to the age of sixteen years. He finds that the Wolffian tract persists in a far greater proportion of cases than has heretofore been taught. The tracts consisted of single ducts with cylindrical epithelium, well-marked lumen, and a muscular wall of three layers (inner and outer longitudinal and middle circular). This was the case in thirty-two of the specimens, while in sixteen others the muscular bands were solid semilunar masses. The right side seems to be favored more than the left, as the involution is more advanced on the latter. The tract sinks into the wall of the uterus about midway between the os internum and fundus, having passed by spiral turns from the broad ligament to the body of the uterus. Thence it passes laterally until it reaches the lower end of the cervix near the cervical canal; from this point it again passes to the side, bending horizontally in the vaginal wall beneath the mucous membrane. With reference to the development of the uterine mucosa in infants, the author shows that the mucous glands are very sparse in the body of the viscus, whereas the cervical glands are well developed.

**Headache and Eye Affections.**—Dr. S. D. Risley (*Journal of the American Medical Association*, September 23d) draws the following conclusions: (1) Abnormalities of the ocular apparatus are in a large group of patients the sole and sufficient cause of headache. (2) Abnormalities of vision may be the unsuspected cause, and therefore the absence of symptoms obviously referable to the eyes does not exclude them as an etiological factor in headache, insomnia, vertigo, petit chorea in children, and certain stomach derangements. (3) The recent or sudden development of symptoms, after attacks of severe illness, as typhoid fever, the exanthemata, etc., or in association with more or less acute exacerbations of some general dyscrasia, is not sufficient evidence against ocular participation in causing the symptoms. (4) The participation of the eyes as an etiological factor in headache can be positively excluded only in the absence of ocular disease or after the most painstaking correction of any existing error of refraction or abnormality of binocular balance. (5) For the relief of reflex symptoms accurate corrections are essential, and these can be secured only by the more or less prolonged use of a strong cycloplegic. (6) Immediate relief by these corrections in a large group of patients is not to be expected, since the pain is frequently due to associated pathological conditions of the fundus oculi, and these require time for cure.

**Post-Apoplectic Hemihypertonia.**—Spiller (*Philadelphia Medical Journal*, December 16, 1899, p. 1188) reports a case presenting tonic spasm of one side of the body, associated with a little weakness, without contracture, developing after an apoplectic seizure, and probably due to irritation of the motor fibres at some point below the motor cortex. The patient was a girl, nineteen years old, who, at the age of three months, had repeated convulsions followed by unconsciousness. When the child began to walk, at the age of ten months, deficiency in power on the right side was observed, the movements being spastic, and this condition had increased progressively. The right lower extremity was spastic, the toes of the right foot being usually flexed in tonic spasm of varying intensity. The right hand at rest in the lap was often slightly flexed at the wrist, and the fingers were slightly flexed at all the articulations, and sometimes it retained this position for a long time. Attempted movement in the right upper extremity from the shoulder was effected without difficulty, but the right wrist became strongly flexed and sometimes the hand was drawn around so that its dorsum or its palm was turned away from the body of the patient. Attempts at movement with the left hand were attended with change in the position of the right hand and fingers from flexion to extension. Flexor predominated over extensor spasm. The condition was aggravated by excitement. The right upper extremity was smaller than the left. Similar tonic spasm occurred also in the lower extremity and in the face on the same side. Intelligence, speech, and sensibility were unaffected.

**Lesions of the Lateral Sinus Resulting from Injuries of the Head.**—Gangolphe and Piery (*Revue de Chirurgie*, 1899, No. 9) report a case of injury to the head with laceration of the lateral sinus, together with seven other cases collected from the literature, and as a result of their study conclude that such lesions may be caused by a double mechanism—namely, by laceration under the influence of a splinter of bone or of a foreign body, and by rupture in consequence of separation of the fragments of fractured bones. As a result, hemorrhage takes place and a clot forms between the dura mater and the calvarium. The seat and the extent of the clot are dependent in part upon the adhesions of the dura mater and in part upon its detachment before the hemorrhage. Frequently there coexists with the extravasation a preceding semifluid, currant-jelly intra-arachnoid effusion, covering the surface of the hemisphere opposite to the injured sinus. The symptomatology of lesions of the lateral sinus are most variable; it may at times be that of central compression and at other times that of an attack of apoplexy due to cerebral hemorrhage. Not only is the diagnosis of the sinus injured most often impossible, but often also the presence of an intracranial hemorrhagic effusion from injury of a vessel cannot be recognized, especially when the symptoms of apoplexy as from cerebral hemorrhage are present. In cases of difficult diagnosis, even when only a knowledge of an apoplectic seizure and of previous traumatism is obtainable, steps should be taken as if the existence of hemorrhagic intracranial extravasation of traumatic origin was assured. If a lesion of the lateral sinus is certain or can be presumed, one or two courses should be pursued. If the sinus is exposed, the wound is tamponed after careful removal of splinters or foreign bodies. If the sinus is not exposed, trephining should be undertaken at or near the point of traumatism, independently of the indications afforded by cerebral localization. These indications may even mislead and cause the application of the trephine at a point remote from the seat of hemorrhage. When the lesion is found, the sinus is tamponed with iodoform and gauze.

**Clinical Study of the Functional Activity of the Stomach.**—As a result of a carefully conducted investigation, Pfaundler (*Deutsches Archiv f. klinische Medicin*, B. 65, H. 3, 4) points out that if, after a given time following the ingestion of a test meal of measured amount, the hydrochloric-acid content of the mixed gastric contents be determined, the following

estimations can be made: (*a*) The total amount of gastric juice and the amount secreted during the various digestive periods; (*b*) the duration of the secretion of gastric juice containing hydrochloric acid; (*c*) the hydrochloric-acid content of this secretion; (*d*) the volume of the material emptied by the stomach into the intestine during the different periods of digestion. The information thus acquired furnishes a rational basis for comparing the activity of the healthy and the diseased stomach with regard to their secretory and motor functions. The values for a stomach with normal chemical activity are as follows:

| | Test Dinner. | Test Breakfast. |
|---|---|---|
| Total amount of gastric juice secreted. | 595.5 c.c. | 105.5 c.c. |
| Duration of the secretion, about .. | 4 hours. | 1½ hours |
| Hydrochloric-acid content of the acid gastric juice. | 0.3514 per cent. | |
| Volume evacuated from the stomach into the intestine. | Hourly, approximately evenly, on the average, 281.6 c.c. | Half-hourly, 90.1 55.1-11.4 c.c. |

The healthy stomach secretes in the first half-hour or hour after the ingestion of the meal the greatest amount of gastric juice; during the succeeding period the amount diminishes and, at least approximately, steadily. In the digestion of a test meal consisting of soup, meat, potato, bread, and water, fermentation lactic acid (and possibly other organic acids) appears in the normal stomach, and its relative amount in the mixed contents may reach as much as one per cent. The acid gastric contents normally are gradually neutralized toward the close of gastric digestion by a secretion poured out in the pyloric antrum, perhaps from the pyloric glands. In the presence of hyperacidity (at least in one variety of this functional disturbance) more gastric juice is secreted in a unit of time and the production of this juice lasts longer than under normal conditions. Probably deficient or retarded neutralization of the gastric contents in the last period of digestion takes part in the pathology of this disorder.

**Gonorrhœal Endocarditis.**—Loeb (*Deutsches Archiv fur klinische Medicin*, B. 56, H. 3, 4, p. 411) reports a case of gonorrhœal endocarditis, from a consideration of which and of the cases recorded in the literature he expresses the opinion that in rare instances of gonorrhœa endocarditis develops, either in direct connection with the virulent urethritis or, more commonly, as an associated manifestation of so-called gonorrhœal rheumatism. Apart from isolated cases in which bacteriological examination discloses the presence of steptococci in the deposits upon the valves, and which must be considered as pyæmic, gonorrhœal endocarditis is a true metastasis, dependent upon the activity of the gonococcus. The disease appears in two forms, verrucose and ulcerative. In the former, which is followed by valvular lesion, in some instances also with complete restoration of tissue, the mitral valve is usually involved, while in the ulcerative variety of the valves of the left ventricle, the aortic are almost always attacked and the pulmonary with comparative frequency. Ulcerative gonorrhœal and post-gonorrhœal endocarditis rarely attacks normal valves, but is usually engrafted upon a preceding endocarditis. As with ulcerative endocarditis in general, the gonorrhœal variety also appears to occur more commonly in women than in men.

**Ptosis.**—Ptosis may be acquired from (1) over weight of the lid, due to hypertrophy, accumulated fat, or disease; (2) spasm of the orbicularis; (3) paralysis or paresis due to (*a*) traumatism to the levator palpebrarum or to its motor nerve; (*b*) disease, either central or peripheral, of the muscle or its motor nerve; (*c*) hysteria. Ptosis may be congenital from (1) overweight of the lid; (2) paralysis or paresis due to imperfect muscular development of the levator palpebrarum. Operations for relief of ptosis may be classified as: (1) Removal of a portion or shortening of the skin of the lid. (2) Interference with the action of the orbicularis. (3) Advancement or shortening of the levator palpebrarum. (4) Substitution of the action of the occipito-frontalis for that of the levator palpebrarum: (*a*) by direct union of the tissues of the lid to the tendon of the occipito-frontalis by means of artificial cicatricial tendons, or permanent sutures; (*b*) by direct union of the tissues of the lid to the tendon of the occipito-frontalis. (5) By substitution of the action of the superior rectus for that of the levator palpebrarum.—Dr. Matthias Lanckton Foster (*American Journal of the Medical Sciences*, December).

**The Presence of Bacteria in Butter and Other Milk Products.**—As the result of a series of experimental observations, Weissenfeld (*Berliner klinische Wochenschrift*, November 27, 1899, p. 1052) found tubercle bacilli in three out of thirty-two specimens of butter examined, and various other bacteria (cocci, diplococci, and bacilli) in a number of additional secondary products of and substitutes for milk.

**Typhoid Fever Complicated by Thyroid Suppuration and Orchitis.**—Murray (*Philadelphia Medical Journal*, December 16, 1899, p. 1191) reports the case of a man, twenty-two years old, in which in the second week of an attack of typhoid fever the previously enlarged thyroid gland became painful and subsequently underwent suppuration, pus containing typhoid bacilli being evacuated on incision. In the fifth week of convalescence inflammation of the right testicle was observed, which, however, subsided entirely in the course of ten days, without effusion or other complication.

**Paroxysmal Hæmoglobinuria.**—Mannaberg and Donath (*Deutsches Archiv fur klinische Medicin*, B. 65, H. 3, 4, p. 285) report three cases of paroxysmal hæmoglobinuria in which they found, on agitating the blood and on ligation of one extremity, diminished resistance of the red blood corpuscles as compared with normal blood. The differences, as shown by control observations, were not absolute, but merely quantitative. The attacks could not be aborted by amyl nitrite. The blood cells also exhibited diminished resistance to carbon dioxide, although here also the differences were quantitative. The secretion of a hæmolytic ferment on the part of the vessel wall during the paroxysm of hæmoglobinuria is considered improbable. In two cases examined, hæmoglobinæmia was found in the blood of the periphery.

**Appendicitis.**—Dr. Maurice H. Richardson (*American Journal of the Medical Sciences*, December) makes the following summary of a very interesting and complete article on appendicitis: 1. Should every case be operated upon as soon as the diagnosis is made? As a rule the appendix should be removed if the diagnosis is made in the first hours of the attack. After the early hours operation is advisable: (1) If the symptoms are severe, and especially if they are increasing in severity; (2) if the symptoms, after a marked improvement, recur; (3) if the symptoms, though moderate, do not improve. The wisdom of the operation is questionable: (1) In severe cases in which an extensive peritonitis is successfully localized and the patient is improving; (2) in cases which are at a critical stage, and which cannot successfully undergo the slightest shock. 2. Should the appendix be removed in any case? It should not be removed: (1) In localized abscesses with firm walls; (2) when the patient's strength does not permit prolonged search. It should be removed whenever the peritoneal cavity is open, unless the patient's condition forbids. The appendix should be removed in all cases as soon as the inflam-

matory process has had time to subside completely—in from two to three months after the attack. In cases simply drained, the scar tissue should be excised, the appendix removed, and the wound securely sutured.

**The Relationship of Membranous Rhinitis to Diphtheria.**—Yonge (*Practitioner*, December, 1899, p. 652) reports a case of membranous rhinitis in which diphtheria bacilli could not be found in the nasal secretion, and expresses the opinion that this disease (not including primary nasal diphtheria) is commoner than is usually supposed, cases being overlooked owing to the mild constitutional symptoms, or being regarded as catarrhal rhinitis. The disease may occur in one of two forms, which concur in the local appearances, the prolonged course, and the mildness or absence of constitutional symptoms, but differ in the presence or absence of diphtheria bacilli and in their power of infection. The form associated with diphtheria bacilli is considerably more common than the simple form, and is a mild local manifestation of diphtheria, differing sharply, however, from the usual form of primary nasal diphtheria. Inasmuch as the two forms of membranous rhinitis are indistinguishable clinically, a bacteriological examination should be made in every case, and isolation of the case practised, at least until the result of the examination is learned.

**The Management of Surgical Injuries to the Ureter.**—Dr. Beverly MacMonagle (*American Journal of the Medical Sciences*, December) draws the following conclusions: 1. Surgical injuries to the ureter during extensive operations on the pelvic and abdominal viscera are comparatively frequent, and are found to occur most often during hysterectomies. 2. These injuries can often be prevented by special care both before and during the operation. 3. In uretero-vaginal fistula great care must be taken to have the urine aseptic before undertaking the operation for repair. 4. In uretero-vaginal fistula repair through the vagina should be first tried. Failing in this, immediate repair by anastomosis or implantation into the bladder is to be preferred. 5. When injuries occur during abdominal operations, immediate repair by anastomosis or implantation should be undertaken. If the condition of the patient is low, implantation on the skin should be done with the view of future operation. 6. When anastomosis or implantation cannot be accomplished, implantation in the other ureter or bowel is preferable to implantation on the skin. 7. Tying the end of the ureter, with a view to atrophy of the kidney, is not advisable. 8. Nephrectomy should be practised only as a last resort. 9. The results of the different methods of uretero-anastomosis and bladder implantation have been about equally successful.

**The Prevention of Shock in Surgical Operations.**—Moynihan (*British Medical Journal*, November 5, 1899, p. 1471) describes briefly as follows the measures that he would recommend for the prevention of shock: The operating-theatre, if in a hospital, should have a temperature of from 70° to 75° F., and the patient should be placed on a table warmed by a current of sterile hot water. As an additional, though not an invariable, adjunct to these means for retaining heat the upper and lower limbs of the patient may be bound in hot cotton-wool and flannel bandages. Strychnine is administered hypodermically before the anæsthetic or the operation commences, the dose being modified according to circumstances. A dose of ♏x. of the solution of strychnine (gr. $\frac{1}{15}$) is usually given at first, and during the operation ♏v. may be given when required; as much as ♏xxx. (gr. $\frac{1}{4}$) may be given without harm. Ten, fifteen, or twenty ounces of hot saline solution are introduced into the rectum, with or without a small quantity of brandy. As soon as the patient is under the influence of the anæsthetic the infusion of saline solution, to the extent of from one to four pints, may be begun. If, after the operation, the patient is at all collapsed, it is important to postpone removal to the wards.

**The Hæmostatic Value of Gelatin.**—Nichols (*Medical News*, December 2, 1899, p. 705) reports a case of hæmophilia in which profuse and long-continued hemorrhage from an accidental wound ceased immediately upon local application of sterile liquefied ten-per-cent. gelatin. As a result of his experience, together with that recorded in the literature, he expresses the opinion that while it is perhaps too early to make a final estimate of the value of gelatin as a hæmostatic, if such successful and remarkable results can be constantly obtained as have been noted by a number of observers, it is certain that the agent will prove of great value in the treatment of some serious and otherwise intractable conditions. The material should not be looked upon as specific in any class of cases, nor should it supersede ordinary methods of hæmostasis. In cases that resist other methods of treatment—and such cases are usually serious and even desperate—the use of gelatin offers some, if only a forlorn, hope of success. If but a portion of cases of hæmophilia which is such an appalling and disastrous complication, or of inoperable aneurisms the treatment of which has heretofore been at best uncertain, yield to this agent, any proportion of lives thus saved, however small, will be ample justification for the use of gelatin.

**The Prevention of Tuberculosis.**—Tonta (*Berliner klinische Wochenschrift*, November 27, 1899, p. 1057) formulates the following rules for the prevention of tuberculosis: 1. Periodic disinfection of all places largely frequented by the public, such as the various forms of conveyance, or apartments in which many persons congregate, as, for instance, schools, halls, churches, baths, cafés, restaurants, institutes, orphan asylums, hotels, barracks, libraries, reading-rooms, convents, waiting-rooms, hospitals, dispensaries, stores, carriages, cars. 2. Forbidding expectoration in all of the places mentioned, and providing cuspidors containing disinfectants. 3. The provision of special places for children to play, to be strewn with gravel, in order to prevent the children from playing in places to which tuberculous patients may gain access and disseminate tubercle bacilli. 4. Whitewashing and disinfecting rooms and dwellings in which tuberculous patients had lived or died. 5. Annual examinations of all persons attending schools and academies, or engaged in offices, institutes, or factories. Such examination should be made in the hospitals by local physicians, and those found tuberculous should be referred to a sanatorium or hospital, and official notice should be given of such cases. 6. The establishment of public institutions for treatment, with the co-operation of private support, beneficial societies, life-insurance societies, etc. 7. Hygienic instruction of tuberculous patients in hospitals and sanatoria in order to avoid infection not only of themselves, but also those with whom they come in contact. 8. Isolation of cases of pulmonary disease in the military and general hospitals, and, if possible, the erection of separate pavilions susceptible of especial care and of disinfection. 9. Preventing persons with pulmonary disease from bathing with healthy individuals, and the establishment of special bathhouses for cases of pulmonary disease under medical supervision. 10. Removal of cases of pulmonary disease from the schools and their transfer to colony farms, where attention to rational treatment and instruction may be given. 11. The formation of a proper committee to send the chil-

dren of poor persons suffering from or dead of tuberculosis into the country, and thus removing them from houses that have become foci of infection. The children in rich families should likewise be removed from their accustomed sphere of activity for some time. 12. Improvement in the hygienic and nutritive conditions of the poorer classes by the establishment of public kitchens, asylums for the homeless, public baths, etc. 13. Improvement of the nutrition and the hygiene of members of poor families in which pulmonary tuberculosis exists. The linen of the patients should be thoroughly disinfected before they are mixed with other linen. 14. Efforts should be made to prevent the marriage of unduly youthful persons whose appearance indicates the possibility of tuberculosis. Persons whose sputum contains tubercle bacilli should be absolutely forbidden marriage. 15. Obligatory periodic examination of domestic animals that are attacked by tuberculosis, and are capable of conveying the disease to other animals or to human beings; otherwise removal or destruction of the diseased animals. 16. Monthly examination of the stables: hygiene of the kitchen, of milking, and of milking-utensils; the greatest care in the dairies. 17. Increase in the number of inspections and supervision of the markets and slaughter-houses. Establishment of examination stations at boundary lines for imported animals. 18. Rigid regulations with regard to manufactured products. 19. Instruction in hygiene in all public schools. 20. Each school-child should possess its own drinking-cup, as well as a towel, and kissing among the children should be interdicted. 21. Instructions to second-hand dealers in books, clothing, and other articles, to practise thorough disinfection. This should also be applied periodically to books in libraries, as well as to articles for common use in schools or elsewhere.

**Traumatic Paralyses of the Shoulder and the Arm.**—As the result of a clinical investigation, Mally (*Revue de Chirurgie*, 1899, No. 10, p. 436) concludes that among the post-traumatic paralyses of the upper extremity, a certain number only appear due to neuritis from extraneous influences. Quite as important a group are of reflex origin. Among nerve-root paralyses a certain number develop, like myelitis, from the effects of traction upon the nerve-roots, and clinical experience would seem to show that certain traumatisms may directly injure the spinal cord and cause paralyses of myelopathic character, and these it is proposed to designate traumatic myelopathics.

**Tumor of the Pituitary Body.**—Walton, Cheney, and Mallory (*Boston Medical and Surgical Journal*, December 7, 1899, p. 565) report the case of a man, twenty-five years old, who presented peculiarities of growth suggestive of congenital defect of the pituitary gland, in which attacks of migraine accompanied by hemianopsia had existed for so long as at first to exclude an organic basis. Later, there was persistent deficiency of vision involving primarily the temporal field of one eye only; subsequently extending to the nasal field of the other eye, and giving rise to homonymous hemianopsia. Still later there was loss of color field on the otherwise unaffected side of one eye (hemiachromatopsia). During the progress of the case there was loss of sexual power, impairment of vision, and optic atrophy, the ocular symptoms with the persistent headache first establishing the diagnosis of tumor. Toward the end appeared vaso-motor symptoms, somnolence, physical weakness and apathy, and lack of mental grasp From a study of this case and of others recorded in the literature, the conclusion is reached that congenital peculiarities in growth resembling those of acromegaly, but occurring in otherwise healthy individuals, may point to structural defect of the pituitary gland, a defect sometimes furnishing the starting-point for new growth later in life. The occurrence of pituitary tumor without definite symptoms of acromegaly does not necessarily disprove a connection between this organ and this disease, for the persistence of even a small amount of healthy gland tissue is sufficient fairly to carry on the function of the pituitary body. The combination of general symptoms of new growth with optic atrophy and loss of the temporal field of vision makes the diagnosis of pituitary tumor almost certain. Hemiachromatopsia is not necessarily of central origin.

**For the Removal of Foreign Bodies from the Nose and Ear.**—Sturrock (*British Medical Journal*, November 25, 1899, p. 1473) recommends the following mode of procedure: The presence and approximate situation of the foreign body having been ascertained, a piece of india-rubber tubing, rather less in diameter than an ordinary lead-pencil, varying in length from one to three inches, and attached to the nozzle of a brass syringe, is introduced into the nostril or meatus, as the case may be, and brought into contact with the foreign body. The piston of the syringe is then pulled out for a sufficient distance to create a vacuum in the tubing, and thus to draw the foreign body into or against its free end. The syringe is then withdrawn, and with it the foreign body attached to the tubing. In some cases it has been found advantageous to dip the tubing into glycerin before insertion, in order to diminish the chances of air entering between the tubing and the foreign body.

**Suppuration of Hydatid of the Liver with Rupture into a Bronchial Tube. Drainage and Removal of the Cyst Wall through an Incision into the Lung.**—Jones (*Lancet*, November 25, 1899, p. 1435) has reported the case of a girl, eight years old, who presented a smooth, elastic, rounded tumor in the right epigastric region, partly under cover of the lower sternal ribs, and extending downward to within three and a half inches of the umbilicus. Above, the tumor was found to be continuous with the liver. There were no pain or tenderness over the swelling, no hydatid vibration, no jaundice, no ascites, and no albuminuria. The spleen was not enlarged, the heart-sounds were normal, and the apex-beat was in its usual situation. There was no pyrexia. The child's general health was reported to be good, but she complained of shortness of breath, and of feeling tight across the stomach, especially after meals. The swelling had been noticed for nearly two years, but it had not perceptibly increased in size during six months, since the removal of some of the fluid contents. Operation was declined, and after two months dry cough developed. The dyspnœa became more marked, the tumor painful and tender, and the temperature constantly raised, but there were no definite rigors. After an additional short time the patient was seized with acute pain in the right infra mammary region, accompanied by vomiting. On examination, the upper margin of liver dulness, which had hitherto been at the upper border of the fifth rib, could not be defined, the dulness being found to extend above the nipple to the extent of one and a half inches. There were well-marked signs of consolidation of the lung in front, and a pleuritic rub over the infra-mammary region of the affected side. In the course of a few more days the patient had a severe rigor with marked elevation of temperature, and followed by profuse perspiration. Vomiting persisted, and apparently was independent of the ingestion of food. The cough was worse, and small quantities of rusty sputum were expectorated. Rigors were repeated, and diarrhœa set in. The cough became persistent and painful, but the vomiting was much less Jaun-

dice of the conjunctivæ appeared, and enlarged veins became visible over the front of the lower part of the right chest. Immediately below and internal to the right nipple some œdema of the skin appeared, which gradually extended over the whole of the front of the right chest. Loud moist sounds could be heard over the lower part of the front of the right chest. The tumor was still painful and tense. The child was seized with choking and became collapsed, following a prolonged attack of cough, with the expectoration of about an ounce of sputum of the color of prune-juice, and of most offensive odor. A repetition of the paroxysm of cough was attended with the expectoration of a few drachms of fetid sputum. The cough closely resembled that of whooping-cough, but without the terminal whoop; it persisted for fully a minute longer, ceasing only when the child fainted. The tumor was now found to be much less tense than it had been, and there were no signs indicating adhesion of the swelling to the abdominal parietes. The œdema of the skin covering the chest was looked upon as indicating that the abscess had ruptured into the lung at no great depth from the surface, or else that it had burst primarily into the pleural cavity, and secondarily into the lung. It was, therefore, decided to make an incision at the spot where the œdema first appeared. Without the use of an anæsthetic, and after aseptic preparation, a slightly crescentic incision, one and a half inches long, was made through the whole thickness of the skin. The intercostal muscles were detached from the upper margin of the fifth rib for a similar extent, and a sinus forceps was thrust through the pleura into the lung tissue for a distance of an inch from the external surface of the rib. On opening the blades some fetid pus escaped. Leaving the forceps *in situ*, a scalpel was introduced between the blades, and the pleura and lung tissue were divided horizontally to the extent of the skin incision. This was followed by a slight gush of blood and several ounces of fetid pus. The fourth finger inserted into the wound was found to enter a cavity about the size of a walnut, and from the interior part of which a track descended directly downward. A half-inch drainage tube was inserted, and a gauze-and-wool dressing applied. In two hours the dressings were sodden with the discharge, and on removing them the drainage tube was found to have been expelled. The patient had not expectorated any pus since the incision was made. The drainage tube was reinserted, but before a fresh dressing could be applied a paroxysm of coughing set in, which shortly expelled the tube. The flap of skin was then seen to be sucked in with each inspiration, thus effectually excluding the air, yet permitting a free expulsion of pus. The drainage tube was discarded, and only an external dressing applied. The paroxysms of cough, though now unattended with expectoration, and of less frequent occurrence, were not changed in character. Consequently, some hours later, the patient having rallied somewhat, the wound was dilated and swabbed dry, and a reflected light thrown in. Nothing distinctive could be made out until a paroxysm of coughing caused a gush of discharge. After swabbing out the pus a pearly white substance could be seen at the bottom of the wound. This was not visible when the paroxysm ceased. Considering this substance to be part of the cyst wall, it was decided to wait, and during the next paroxysm seize the cyst wall in the blades of a forceps. This was done, and slight traction exerted. As more of the cyst wall became visible a second pair of forceps was applied behind the first. As traction made during the interparoxysmal periods caused tearing of the cyst wall, it was applied only during the paroxysm. The points of fixation of the forceps were alternately changed as more and more of the cyst wall appeared at the bottom of the wound. After fifteen minutes the whole of the cyst wall was extracted almost intact, four ounces of the fetid pus being discharged, and to the weight of which was attributed the proneness of the cyst wall to tear, for on further examination of the latter its friability was not nearly so great as was at first suspected. In volume the size of the cyst wall was rather larger than a Jaffa orange. A little iodoform emulsion was syringed into the cavity, and a gauze-and-wool dressing applied externally. The character of the cough changed entirely after the extraction of the cyst wall, the pertussis-like paroxysms disappearing. Within a week the discharge had practically disappeared, and in a month the wound had granulated up soundly from the bottom. Slight cough and slight evening rise of temperature persisted for more than two months. When seen nearly four years later, the patient appeared perfectly healthy and free from cough. Slight bulging of the ribs and cartilages still persisted. On auscultation the only adventitious sound heard in the chest was a dry rub in the immediate vicinity of the scar.

**Sequelæ of Ovariotomy.**—Dr. Martin ("Klinische Vorträge," No. 255) gives some of his observations on the sequelæ of ovariotomy, paying special attention to hernia. It is well known that stretchings and irregularities of the abdominal scar develop after all kinds of incision. Probably abdominal scars are the most prone of all to undergo distortion. Often a stitch aperture is the origin of a hernia. This gradually increases till a large rupture is developed with all its well-known characteristics. These are especially serious after extraperitoneal treatment of the stump, abscess formation, and abdominal drainage. Many attempts to avoid such untoward sequelæ have been made. From the major incision of the old surgeons, a change was made to an opening as small as possible. Some operators, Lawson Tait especially, made the incision so small that only two fingers could be inserted. But the resulting scars also stretched. Then the linea alba was thought unsuitable for incision, and so this was made in the rectus muscle itself, either in its outer border or in the flank. The skin was cut crosswise, the fascia and muscles were divided lengthwise. Finally abdominal binders were thought to give a perfect support to the scar, and numerous varieties were tried, but they did not yield the desired results. It was early observed that the scars following suppurating wounds as well as those after extraperitoneal treatment of the stump and drainage, were especially disposed to stretch. The first progressive step was taken in the introduction of asepsis. Next, instead of suturing the abdominal layers *en masse*, the separate layers were stitched together one by one. Martin makes his incision exclusively in the linea alba. It is noticeable that most hernias resulting from scars do not cause much trouble, at least if a suitable binder is worn, though there are the same discomforts as in other ruptures—namely, pain on pressure, nausea, a feeling of weight, nervous symptoms, etc. Generally, the patient's capacity for work is interfered with. An effective treatment of beginning hernia is not known. Martin has used bands of adhesive plaster to avoid the stretching of the stitch punctures. Many surgeons employ abdominal binders; others make use of a suitable corset with an elastic lower border. In the worst cases, of course, operative treatment may be advised. For small tumors and inflammatory ovarian swellings of favorable position, the vaginal incision is always feasible. But the number of cases amenable to this treatment is quite limited. Martin speaks also of the treatment of the troublesome general symptoms which often follow ovariotomy. This has been varied. Fresh preparations of ovarian substance have been tried;

experiments have also been made on animals of transplanting ovarian tissue. Decidedly varied results have been obtained. Martin himself, in some of his cases, has made use of tablets of ovarian substance with differing results. He cannot, from his own experience, promise a brilliant outcome for this treatment. He gives certain dietetic directions to all his ovariotomy patients, advising a carefully regulated life, and avoidance of heating drinks such as alcohol, coffee, and tea; and he also recommends energetic exercise and faithful attention to the bowels and kidneys. He closes his monograph by expressing the hope that in the future some internal medicinal treatment may be discovered to benefit those now operated on for removal of the ovaries.

**The Geographical Tongue in Childhood.**—Dr. Henry Böhm ("Klinische Vorträge," No. 249), after giving a short history of the geographical tongue in childhood, sums up certain conclusions he has reached in his study of this subject. He states that, so far as he knows, the comparison of a certain affection of the tongue with the contours of a map was first made by Santlus. Moeller had observed prior to that six cases of chronic excoriation of the tongue, in five of which the patients were afflicted with tænia or bothriocephalus. The affection was, however, exceedingly painful, while the geographical tongue is described as almost invariably painless. For this reason "Moeller's glossitis" has been given a special place in the text-books on this subject. On the other hand, it would seem that the five cases observed by Betz would have to be classed among those of geographical tongue. He proposes the designation of pityriasis of the tongue for the affection observed by him. In looking over the literature of the subject we find interesting contributions by Bergeron, Gubler, who conjectures concerning a parasitic origin of the disease; Gautier, Caspery, Unna, and others. On the basis of the observations and investigations made by the author of the paper, he arrives at the following conclusions: The so-called geographical tongue is a rather common affection in childhood, occurring most frequently in children under two years of age. The anatomical basis of the disease is as yet unknown. It is observed in the majority of cases soon after birth, in a small proportion within the first year, and rarely in later childhood. The duration of the affection extends over years, although a temporary disappearance of the same for a longer or shorter period has frequently been noticed. In about two-thirds of the cases observed by the author, he found suspicious symptoms pointing to tuberculosis, at times with and at times without hereditary taint. The question whether on this account the disease can be brought into closer relation with scrofula or tuberculosis, although plausible, cannot be definitely decided as yet. The chronic course of the trouble and its gradual disappearance in later childhood furnish an analogy with the long-continued and often recurrent catarrhs seen in other mucous membranes in cases of scrofula or tuberculosis. The fact that only two-thirds of the cases observed by Böhm showed symptoms of scrofula or tuberculosis does not, he thinks, necessarily argue against the assumption of a relation between the process and the constitutional disease, nor do the five fatal cases, of which only one had tuberculosis, prove anything against this assumption.

**Retroversion of the Uterus and Chronic Inflammation of its Appendages in Consequence of Bodily Strain.**—Camillo Fürst ("Klinische Vorträge," No. 253) discusses the effects of bodily strain on the uterus and its appendages. His observations show that considerable transient, as well as long-continued and moderately increased, intra-abdominal pressure is a prominent factor in the development of this condition. On the other hand, there is no doubt that previous pregnancies furnish the chief predisposition. It is well known to every gynæcologist that retroversion of the uterus in the virgin is by no means a rare occurrence among the better classes, a fact which must be attributed to the long-continued sitting posture in a tightly laced condition that young girls assume during school hours. If such women adopt the bicycle as a means of recreation, they will find its effects invariably baneful. The author considers that swimming is the exercise most apt to counteract these injurious effects. Furthermore, Fürst has found that there is a certain immunity against retroversion in women with occupations in which the intra-abdominal pressure is lessened for continuous periods, as, for example, in floor-scrubbing. He has also noted that women in the lower walks of life, who are obliged to do their own housework, and who, while their work may be quite heavy at times, are forced to change their posture continually, are no more frequently subject to retroversion, despite all their hardships, than their better-situated sisters. For these reasons the author has for many years made use of the knee-elbow position for suitable cases of this description. Particularly well adapted for this treatment are those cases in which manual reposition is impossible without narcosis, at least in the beginning, on account of extreme hyperæmia and sensitiveness of the uterus, or on account of extreme softness of the organ. With reference to inflammation of the uterine appendages, the author shows by his statistics that the cause for this condition is to be found principally in great bodily exertions, such as lifting heavy burdens or sustaining concussions. A remarkable point shown by his statistics is that parametritis occurs more than twice as often on the left than on the right side. Such left-sidedness seems, in fact, to be characteristic of parametritis. He thinks it quite possible that this is due to the more frequent use of the right upper extremities in the execution of heavy work, since thereby the lower part of the trunk assumes such a position as to force downward the left parametrium farther than the right because of the increased intra-abdominal pressure. His experience has shown that in instances when both arms were equally employed, the disease occurred with almost equal frequency on the right and left sides.

**The Pathology of Paralysis Agitans.**—Dana (*American Journal of the Medical Sciences*, November, 1899, p. 503) reports a fatal case of paralysis agitans, with autopsy and a careful histological examination of the nervous system, disclosing the following anatomical changes: There was some general atrophy of the cord, with moderate increase in the connective tissue, and some dilatation of the perivascular lymph spaces. There was no special thickening of the blood-vessels, either veins or arteries, and no meningeal thickening. The anterior cornual cells exhibited pronounced changes, consisting in atrophy, pigmentation, and vacuolization, loss of dendrites, and diminution in the richness of the plexus formed by the dendritic processes, the alterations being most marked in the upper cervical and lower dorsal regions. Clarke's columns were not markedly affected, while the cerebral cortex exhibited slight degeneration of its cells, and the olivary nerve-cells also were degenerated. The peripheral nerves were normal, while the muscles and end-plates exhibited some fatty degeneration. Of the two views prevailing—namely, that paralysis agitans represents merely a premature condition of senility, and that the changes are the same as those found in extreme old age, the difference being a matter of degree and

not of kind, on the one hand; and that the nervous system presents changes that differ from those of senility, although these have not yet been thoroughly worked out, on the other hand—Dana is inclined to accept the latter. In his opinion the history of the disease indicates that it is primarily a parenchymatous nervous disorder, due perhaps to the remote or secondary results of some infection or intoxication. Rheumatism is common in the history of cases of paralysis agitans, and there are many facts in the clinical course of the disease that suggest a relationship between paralysis agitans and that form of rheumatic manifestation which is known as rheumatoid arthritis.

**A Contribution to the Study of Epidemic Diarrhœa.**—Dr. Arthur Newsholme (London *Lancet*, December 2d) summarizes an article on this subject from the evidences adduced as follows: (1) It is clear that towns with a high temperature and a deficient rainfall, especially in the third quarter of the year, suffer severely from diarrhœa. This relationship is so close that the towns may be classified meteorologically in the order in which they ought to stand in reference to diarrhœa, and their true relative position as to domestic and municipal sanitation may be ascertained when we know whether they occupy a better or worse position on the lists of towns than that which their meteorological place would indicate as rightly belonging to them. (2) It is clear that among populations living on impervious and rocky soils diarrhœa is not so prevalent, probably because polluting fecal and other organic impurities do not cling to, or soak into, such soils. (3) Diarrhœa is most prevalent where the removal of ditch and house refuse is the least satisfactory. The exceptionally good position of certain towns in which pail-closets are largely used must be regarded as due to the favorable climatic and physiographic position of these towns, probably aided by efficient municipal scavenging; and it is most certain that their position might be still further improved by the general adoption of the water-closet system. The fundamental condition favoring epidemic diarrhœa is an unclean soil, the particular poison from which affects the air and is swallowed, more commonly with food, especially milk. In other words epidemic diarrhœa is, like typhoid fever, a "filth disease." There are, however, certain points of contrast between the two diseases. In the annual summary of the registrar-general for 1898 is a table giving the average death rates for diarrhœa and enteric fever, 1888–1897. The clew to the difference of incidence of the two diseases will, I think—apart from the fact that enteric fever is a disease principally seen in adults, who are in the habit of taking infected foods not eaten by infants—be found in the view that the causation of diarrhœa is closely associated with surface pollution of the soil, that of enteric fever with less superficial pollution of the subsoil from cesspools and leaky drains, as well as from privy-middens. It will be noted that I have hitherto refrained from discussing the influence of artificial feeding with cow's milk in the causation of diarrhœa. Milk is, however, not the actual cause of diarrhœa. It is a vehicle of infection, just as mosquitoes are the vehicles in malaria, or rats in plague. Our ultimate researches ought to be directed toward elimination—if it be practical—of the actual conditions under which the contagia of these diseases are able to live.

**The Prognosis of Appendicitis, with Notes of Two Hundred Cases.**—Dr. H. A. Caley, at the meeting of the Medical Society of London (London *Lancet*, December 2d), stated that there were two factors to be considered in regard to the pathological basis of prognosis: (1) The nature and course of the appendix lesion regarded from the point of view of relative infectivity; and (2) the extent and nature of any resulting peritoneal infection which depends for the most part upon the actual lesion in the appendix, and in part also on its position and on certain special modifying conditions. Of these two, the most important direct prognostic factor was the peritoneal one. Two hundred consecutive cases treated in the medical and surgical wards of the St. Mary's Hospital were adduced to illustrate this. Of these, ninety-nine were cases of simple appendicitis and perityphilitis—*i.e.*, cases in which the peritonitis was localized and non-suppurative; all ended in recovery. Thirty-one were cases with localized suppuration, and of these twenty-nine patients recovered and two died. Twenty-three were complicated by general peritonitis, of which three patients recovered and twenty died (many of these were in a practically hopeless condition when admitted). Forty-two were examples of chronic and relapsing appendicitis (in thirty-seven the appendix was removed), and all these resulted in recovery. In the remaining five cases there were special complications, such as intestinal obstruction, hepatic abscess, and pulmonary œdema; and of these two patients recovered and three died. These figures illustrate the great fatality of appendicitis when general peritonitis is present, and the small mortality in the presence of localized abscess if efficiently treated, and the most uniformly favorable course of mild cases of the disease. The prognostic indications were based on the same features as the diagnostic indications. These might, for convenience of description, be arranged in four groups: (1) Local symptoms, with special reference to pain and vomiting. The severity, distribution, and duration of the pain varied greatly; as a rule, however, in mild cases the pain tended to become localized, whereas in perforative cases it was usually sudden and severe and more generalized. Persistent severe pain was suggestive of a severe lesion, and a sudden increase of pain was an unfavorable turn. Vomiting as a single symptom was more significant than pain. In the majority of cases which did well, vomiting was present only in the initial stage; it tended to subside when the patient was kept in bed and carefully dieted. (2) General symptoms with special reference to the temperature, pulse, respiration, and general condition. The temperature, pulse, and respiration must be considered conjointly, not separately, and the aspect of the patient be carefully noted. The temperature chart by itself is apt to be a fallacious guide, for there might be a subnormal temperature with initial collapse and perforation, or with general suppurative peritonitis. If, however, the type as well as the height of the fever was taken into account and considered in conjunction with the pulse and respiration, it was of prognostic import. A high pulse suggested a severe lesion. In the majority of the less severe cases included in this series the pulse rate was between 80 and 100; in every one in which it was persistently above 120 the attack was severe, and in most cases there was a localized suppuration or a general peritonitis. The importance of a pinched and anxious aspect and restlessness, obvious distress, or collapse was well known. (3) Local signs on physical examination. The degree of impaired mobility of the abdominal wall, the presence of abdominal distention, the distribution of localized tenderness and muscular rigidity were of value in assuming the extent of peritoneal implication. (4) The progress of the case. That was of special importance during the first twenty-four hours in acute cases. In the course of a few hours developments might occur which might have a determining influence in the prognosis and treatment. The prognosis as to recurrences had been given by various authorities in the proportion varying

from thirty per cent. to forty-seven per cent. In general terms recurrences may be expected in about one-third of the cases. The second attack usually occurs within two years, more commonly within one year, of the first attack. The liability to recurrences in a particular case amounts to a practical certainty if there are persistent pain, tenderness, or local thickening—symptoms which are indicative of chronic appendicitis.

**The Early Diagnosis of Aneurism of the Arch.**—I now wish to put on record a method of examination with which I have been experimenting for about three years. Remembering the close proximity of the aorta and œsophagus, and that the latter is exceedingly elastic and compressible, it occurred to me that a large bougie, with the lower end made very distensible, could be passed down opposite the site of the suspected aneurism, and the impulse be conveyed to the elastic end of the tube, and measured. The procedure is a very simple one. The ordinary œsophageal bougie can be covered at the end with gold-beater's skin, and, after a little spraying of the pharynx with a weak cocaine solution, it can easily be passed without danger and violence to the thoracic region. The tube is often distended with water, and connected with a V-shaped tube, which is also filled with water. A few drops of coloring matter will add to the demonstration of the experiment. If the tube is passed down near the cardiac orifice, the heart impulse is sufficient to produce some vibration in the tube, especially if there is hypertrophy; but if the tube is placed approximately opposite the aortic arch, very little impulse is noted in the normal case.—Dr. William Porter (*New York Medical Journal*, December 9th).

**X-Ray Illumination of the Stomach.**—Benedikt (*Wiener med. Presse*, 1899, No. 8) has devised a method which makes it possible within a few moments to transilluminate the stomach and the large intestine. Finding that the normal lung gave much lighter shadowgraphs than those atelectatic or infiltrated with tubercle, and that tumors of the chest as well as the heart itself are always easily seen, the thought occurred to him that an inflated stomach or intestine must give an analogous result. This proved to be the case. The inflation can be accomplished in short space of time by means of a stomach and intestinal tube and a balloon bulb. Viewed then through the fluoroscope the correct size, shape, and position of the stomach are said to be visible, and a tumor of that organ to be as discernible as the heart in a transillumination of the chest. It is claimed also that dilatation, hour-glass contraction, as well as anomalies of position and shape of the stomach can be recognized. The haustra of the large intestine and the contour of its walls are also plainly seen, and here, too, tumors, strictures, and dilatations are recognizable. The small intestines, on the other hand, cannot be inflated with air, and they therefore cannot be seen.

**Indications for Rectal Saline Enemas.**—From experiments and clinical observations, v. Mering (*Die Therapie der Gegenwart*, April, 1899) concludes that absorption from the stomach is dependent upon physical laws (osmosis), while that from the intestines depends upon the activity of the living cells. It follows, therefore, that injections of water into the intestine are indicated whenever the motor function of the stomach is insufficient. This condition is most marked in stenosis of the pylorus. v. Mering also recommends rectal injections in carcinoma, ulcer, as well as in neuroses and catarrhs of the stomach, when there are marked fermentation of the contents and diminution in the quantity of urine voided. Furthermore he sees them indicated when excessive thirst exists, as in diabetes mellitus, exhaustive sweats, profuse diarrhœa, and especially after severe hemorrhages. In the last instance the water replaces that of the blood, and we see in this class of persons the water rapidly absorbed from the rectum. The author recommends immediate injection of one litre of a one-half-per-cent. sodium-chloride solution, after a profuse hemorrhage; the injection to be repeated once or twice at intervals of three hours.

**Condition of the Stomach during Rectal Alimentation.**—Ziarko (*Berliner klin. Wochenschrift*) has inquired into the condition of the mucous membrane of the stomach during rectal alimentation. Winternitz claims that nutrient enemata are useless in ulcer of the stomach, believing that a reflex stimulus to the gastric glands is produced analogous to that from excitation of the gustatory and olfactory nerves, and that gastric secretion is poured out each time. A series of experiments has shown Ziarko that during as long a period as two and one-half hours after administration of a nutritive rectal enema there was no increase in amount of the stomach contents, nor of the acidity thereof. On the contrary the acidity was somewhat diminished. Ziarko thinks this diminution in acidity is due to two factors: suspension of glandular activity and mingling of alkaline mucus from the wall of the stomach.

**Medical (Carlsbad Course) and Surgical Therapeutic Indications in Cholelithiasis.**—Kehr (*Munchener med. Wochenschr.*, 1899, No. 38) divides the cases as follows: (*A*) Medical: (1) acute closure of the ductus choledochus and normal course; (2) inflammatory processes of the gall bladder with or without icterus, which are not too severe or of too frequent occurrence; (3) frequent colics followed each time by passage of stones; (4) gall stones complicated by obesity, gout, or diabetes, or by conditions which would render narcosis dangerous (cardiac, pulmonary, or renal affections); (5) patients who have already been operated upon. (*B*) Surgical: (1) Acute seropurulent cholecystitis or peri-cholecystitis; (2) when there are adhesions between the gall bladder on the one hand, and the intestine, stomach, or omentum on the other; provided, however, that they cause disagreeable symptoms; (3) chronic closure of the ductus choledochus; (4) chronic closure of the ductus cysticus (hydrops or empyema of the gall bladder); (5) gall-stone colics, which, though comparatively mild in character, resist all internal treatment, and by their presence render life a burden to the patient or interfere with his occupation; (6) suppurative cholangitis or abscess of the liver; (7) perforation along the biliary passages and peritonitis; (8) when morphinismus results.

**Hernia Following Abdominal Operations: Its Prevention and Cure.**—Under the above title Dr. A. Lapthorn Smith contributes an interesting article (*Pacific Medical Journal*, November, 1899), in which he summarizes as follows: 1. Hernia is a frequent complication following abdominal section. 2. When it occurs it prevents other women from undergoing a needed laparotomy. 3. It is quite preventable *a*) by leaving in the stitches for one month if the woman is thin enough to allow us to use through-and-through sutures; or (*b*) by using non-absorbable buried ligatures when the woman is fat enough to require two layers of sutures. The writer prepares his silkworm gut by placing it in solid glass tubes, and boiling it. A cut with a file is made in the middle, and just when it is required for use the tube is snapped across. (*c*) by discarding the abdominal drainage tube, and when drainage is necessary, which it rarely is, draining through the vagina; (*d*) by securing accurate

coaptation of the cut edges by marking the places where the stitches are to go before making the incision; (*e*) by taking care that no peritoneum is curved up so as to come between the muscle and fascia of the opposite side. 4. Hernia is easily cured in small cases with a single buried silk worm-gut purse-string suture; and in larger cases by splitting the edges of the ring until the recti muscles are exposed from top to bottom, and suturing them with buried silkworm gut. 5. Patients with buried silkworm-gut stitches do not need to stay in bed more than two weeks, and in some cases less; and they do not need to wear an abdominal belt.

**An Atypical Case of Measles.**—Dr. Frank H. Rowe (*Pediatrics*, August, 1899) reports the case of a girl four years old, sick with fever for four days, whose older sister during the same time had measles. He saw the case for the first time on the fifth day, when the child had 104.5° F. temperature. Fever continued steadily for ten days, and then declined to the normal without the slightest exanthema. Nervous symptoms were marked, with severe headache, delirium, muscular twitchings, rapid respiration, dry cough, uncontrollable diarrhœa, and general typhoidal state. The symptoms began to improve about the eleventh day, and a few days later the child was convalescent, when a younger sister developed an ordinary case of measles. On the fourteenth day of treatment, when the child was considered recovered, a very copious general eruption of measles appeared, which followed the usual course, but without any systemic disturbance.

#### SECTION ON SURGERY.

*Stated Meeting, December 11, 1899.*

CHARLES N. DOWD, M.D., CHAIRMAN.

**Prostatectomy.**—DR. ALEXANDER D. JOHNSON presented a patient, sixty years of age, upon whom he had done prostatectomy. He had been admitted to the Roosevelt Hospital on October 2, 1899. Five years before he had begun to suffer from difficult, painful, and frequent urination. He had been catheterized occasionally to relieve retention of urine. The urine was passed in normal quantity, was cloudy, acid, and contained a very large amount of pus, but no casts. The examination of the urethra showed that the canal was patent. The distance from the bulbomembranous junction to the bladder was markedly increased. There were regularly five ounces of residual urine. The lower edge of the prostate appeared to be within one inch and a half of the sphincter. The patient suffered from moderate fever and had a pulse of about 120 most of the time. His bladder had been daily irrigated, and the urine had been withdrawn by catheter for five days without improvement. On October 7th he had been operated upon under nitrous oxide and ether anæsthesia. After irrigation of the bladder and leaving a few ounces of boric-acid solution in the bladder, this organ had been exposed by an incision two inches long. Through a perineal incision the prostate had been reached, and its capsule incised on either side of the median line, and each half of the prostate enucleated with the finger. The median portion came away easily, still attached to the lateral lobes. At the point of attachment to the urethra mesially the mucous membrane had been torn. The removal of the gland had been accomplished with ease, and the bleeding, while free, had not been alarming. It was found to be an ordinary mixed hypertrophy of the prostate gland. A large soft-rubber catheter had been inserted through the rent in the urethra, and pushed into the bladder. The cavity on either side, as well as the middle portion of the perineal wound, was packed with gauze. The suprapubic wound was closed with deep catgut and superficial sutures. There were no shock and not much pain after the operation. The urine had drained chiefly through the packing for three days, requiring frequent change of the outside dressing. For twenty-four hours this discharge had been blood-stained. The bladder had been irrigated daily with boric acid through the tube until the seventh day, when it had been removed permanently, after which irrigation had been accomplished through the urethra. The suprapubic wound had healed primarily. After the seventh day a No. 32 French sound had been passed through the meatus and into the bladder daily. The patient had been allowed out of bed on the twelfth day. The urine had been voided voluntarily through the urethra on the eighth day, after which the irrigation had consisted of silver solution. Then faradization had been employed, and had seemed to increase decidedly the force of urination and diminish in this way the quantity of residual urine. The perineal sinus had diminished slowly and was now almost completely closed. Now, two months after the operation, his general health was very greatly improved, he having gained fully twenty-five pounds in weight. While this patient's convalescence had been slow, the result would seem to justify even a longer period of disability. He had found the operation especially difficult, but in the future he would probably modify the operation by endeavoring to avoid tearing through the prostatic urethra by shaving off the attachment with a blunt-pointed knife. He would then repeat the process on the other side and introduce a drainage tube through the longitudinal slit in the membranous portion of the urethra. The object of this modification was to secure a more rapid convalescence.

DR. EUGENE FULLER also presented a case of prostatectomy, in a patient from the City Hospital. He was a man sixty years of age, who some time ago had been seized with retention of urine. In one of the metropolitan hospitals perineal drainage had been established, but nothing had been done to the prostate. Of course, as soon as the drainage tube had been removed a perineal fistula had been left, and the patient had been worse than before. There had been a condition of perfect atony of the bladder, and this viscus had been in a very foul state. The speaker said that he was of the opinion that a perineal operation in a case presenting such a condition of a prostate and bladder was more dangerous than a suprapubic operation. If a large prostate was removed under such conditions, there was liable to be a great deal of hemorrhage, and if the bladder was not opened, a great deal of trouble might be experienced in controlling this hemorrhage. Better drainage was secured by having a suprapubic opening. On making the suprapubic incision he had found that, owing to an extensive peritonitis, it had been impossible to expose the bladder except by going through the peritoneum, or by adopting the Trendelenburg transverse method. The latter plan he did not like, and he objected to the former because of the foul condition of the bladder. He had accordingly closed up the suprapubic opening, and had made an extensive perineal operation. The latter had had to be modified because of the existing perineal fistula. He had finally succeeded in getting the large prostate into the cavity of the bladder, and then had seized it with a flat pair of abdominal forceps and had delivered it through the perineum.

Dr. Fuller also presented a man who had had a gonorrhœal urethritis some time ago, and, as a result, so much inflammation and tumefaction that absolute retention of urine had been produced. The inflammatory condition had invaded the capsule of the prostate, and had thickened all the neighboring tissues. The bladder was extremely atonic, and hence, if a severe hemorrhage should occur into such a bladder, it would be very difficult to stop the bleeding. In more than one emergency case of this kind he had made a suprapubic incision in order to let out the rapidly accumulating blood. For these reasons he had made in this case a suprapubic incision in addition to the perineal opening. This method had secured perfect rest of the bladder, and had enabled this viscus to regain its proper tone.

Dr. Fuller then presented a case showing extensive urethral resection. There had been several false passages, and the urethra had been almost cartilaginous for some distance. He did not favor much instrumentation after such operations. In this patient the operation had been done four or five weeks ago, and an instrument had been passed only once since that time; nevertheless urination at the present time was exceedingly satisfactory.

Dr. Forbes Hawkes presented a man, aged seventy-one years, upon whom prostatectomy had been done. When seen one year ago, he had stated that there had been only three attacks of retention of urine in the previous fifteen years. The last attack had been more severe than the others, and catheterization had been difficult and had been accompanied by the passage of blood. The man was straining a great deal at the time. Dr. Hawkes said that he had introduced a large silver prostatic catheter down ten inches, and had then passed over a bar and, after going about two inches further, had finally penetrated the bladder. The spasm had returned in an hour or two, however, and on this account a suprapubic operation had been advised and performed. The bladder had been distended with air before opening it. On incising the viscus, a very large prostate had been exposed. The catheters employed had apparently tunnelled directly through one lobe. Both lateral lobes had been greatly enlarged, but had been readily enucleated. The median lobe had also been enlarged. By passing the fingers down through the right lateral pouch, the finger of an assistant being in the rectum pushing upward, he had succeeded in removing the median lobe without opening the prostatic urethra. There had been comparatively little bleeding and disagreeable reaction. At the present time, the man could sleep ten hours without getting up to urinate, and he evacuated the bladder only three or four times during the day. The only thing complained of was that on sneezing a few drops of urine would appear at the meatus. On the whole, the functional result seemed to be excellent.

**Removal of Floating Cartilage from the Knee Joint.**—Dr. B. Farquhar Curtis presented a young man who had had a floating cartilage removed from his knee joint. There had not been many of the usual symptoms of this condition. Last June the young man had had a traumatic synovitis, which had been treated by bandaging for three or four weeks. He had then remained well until September, when another traumatic synovitis had developed from a slight cause. When that had subsided, it had been found that a mass of considerable size lay to the outer side of the patella. It could be easily rolled about within certain limits, but always returned to its position alongside of the patella. It had been exposed by an incision, and removed. The interesting feature was the structure of this large foreign body—it was pure hyaline cartilage. It had been attached by a pedicle to the lower end of the joint. From its structure one would suppose that it had been chipped off from the joint surfaces by slow necrosis, but the shape of this body was so much like the ordinary synovial fringes, and its attachment pointed so strongly to this origin, that he had been compelled to accept this view. It was now three weeks since the operation. The wound had healed by primary union.

**Loose Cartilages following Trauma.**—Dr. Samuel Lloyd presented a youth of eighteen years, who had injured his knee while jumping in such a way that his weight came upon the right foot. Immediately afterward, he had experienced pain in the knee joint, and had noticed a clicking in the joint. Four weeks ago he had been admitted to the Post-Graduate Hospital and operated upon. Four loose cartilages had been found in the joint, one the size of an almond kernel, and the other three about the size of a pea. He had been allowed out of bed after one week, and the splint had been removed on the tenth day. He had been walking without any splint since that time, and already had a good functional result.

**A Remarkable Deformity of the Shoulder.**—Dr. J. F. Erdmann presented a colored man aged twenty-one years, who, when two years old, had fallen from a baby carriage and sustained an injury of the shoulder, which had left him with a marked deformity. Examination showed that the point of the clavicle was well up toward the back of the right ear. A skiagraph of this remarkable deformity was also exhibited.

**The Operating Cystoscope of Nitze and Caspar.**—Dr. Willy Meyer exhibited this instrument. He said that a description of it had been first published in 1891, but it had not then been obtainable in the market. Casper had made use of the straight cystoscope as an obturator, which could be easily introduced through the central shaft, for example, of a lithotrite. If there was much bleeding, the cystoscope could be quickly withdrawn and the bladder washed out. The snare and other attachments of both the Casper and Nitze instruments were exhibited, and their action demonstrated. In 1896 Nitze had reported thirty cases of tumor of the bladder upon which he had successfully operated with his operating cystoscope. Many of his cases had been operated upon at his office, and without general anæsthesia. In some instances as many as fifteen sittings had been required for the snaring off of the tumor and cauterization of the point of its attachment. Not one of these patients had died under the treatment. The majority of them had been examined within a year or two after operation, but not at a later period. This operator claimed that many of the papillomata of the bladder were benign growths, but the speaker said that he would expect later examination of some of these cases to show recurrences of a malignant nature. The operating cystoscope should prove especially valuable in connection with the operation of litholapaxy, because it could readily detect any fragments remaining behind in the bladder.

**Freudenberg's Modification of Bottini's Prostatic Cauterisator.**—Dr. Meyer demonstrated this instrument, and in doing so expressed his firm conviction that Bottini's operation on the prostate had come to stay. He had done the operation twenty-eight times on twenty-three patients. A patient would not submit to the removal of a small prostate only causing slight retention of urine, but many would be only too glad to submit themselves to the Bottini treatment. It was possible that, in time, this method would enable the surgeon to get these patients at an early stage.

Dr. L. Bolton Bangs said that he had been captivated with the ingenuity of Nitze's instrument, and was interested in its possible application. He had found, however, that such treatment was limited, or of wide

application, depending upon one's view of the pathology of the condition presented. Dr. Meyer had admitted this evening that many of these growths appearing at first benign proved later to be malignant. It was because he shared this view that he had not used these instruments, although admitting that the Nitze method might prove useful for the treatment of the recurrences. In his opinion, the first principle in operating upon tumors of the bladder was that well known to all surgeons—wide and thorough removal of the growth. He was sure that such treatment would be the best for these bladder growths. Regarding the Bottini cutting instrument he said that he knew there were some cases in which it had absolutely failed, and he was now endeavoring to find principles for the proper guidance of the surgeon in the use of this instrument. He had failed with deep and long incisions in relieving at least two of his patients having a fibroid enlargement of the prostate, but in the soft prostate, in which the glandular element seemed to preponderate, the success of the Bottini-Freudenberg instrument seemed to be assured.

Dr. Samuel Alexander said that in order to determine the value of any operation for the relief of prostatic enlargement two questions must be answered: (1) What were the causes of vesical retention and incompetence in cases of prostatic enlargement? (2) How did any good operation relieve it? The principal cause was mechanical obstruction to the flow of the urine, which might be either of a permanent or temporary character. A temporary obstruction was due to œdema of the prostate and prostatic urethra and internal vesical orifice. It was the result of venous stasis. It might occur very suddenly, and in most cases was the direct and immediate cause of sudden retention of urine in prostatics. There were, however, other causes which were equally important, though frequently overlooked. First, there was a displacement of the insertion into the prostate of the fibres of the vesical muscle. As the result, the regular wave of contraction of the detrusor muscle was interfered with, the internal vesical orifice was closed before the bladder has been emptied, and there resulted partial retention with residual urine present. The displacement of the muscular fibres, in their insertion into the prostate, might be due either to growths springing from the lateral lobes and pressing backward into the bladder or downward into the prostatic urethra behind the veru montanum, or to one of the forms of so-called middle-lobe enlargement. He recognized three varieties of this type of enlargement: First, there might be an enlargement in this part limited to the anatomical middle isthmus of the prostate —that is, to that portion which joins the two lateral lobes together and which lies between the mucous membrane of the prostatic urethra, the internal orifice, and the seminal ducts. When this part alone was involved, it pushed upward and backward the mucous membrane and muscular coat of the prostatic urethra at the internal vesical orifice, forming an oval bar at the vesical outlet. As a result of this obstruction, which was usually associated with enlargement of the lateral lobes, that portion of the detrusor muscle whose function it was to empty the lower fundus of the bladder was called upon to do an extraordinary amount of work, and in time it became thickened and hypertrophied, especially at the urethral orifice, though sometimes in the region of the trigone, forming the so-called bar at the neck of the bladder. The second form of middle-lobe enlargement consisted in a growth in the anatomical middle isthmus, with enlargement of the irregularly placed glands at the internal urethral orifice. These latter lay directly beneath the mucous membrane and between the circular fibres of the bladder and the middle isthmus of the prostate. The prostatic tissue in the middle isthmus, and these irregularly placed glands beneath the mucous membrane, had at first no connection, but as the disease advanced the muscular fibres of the bladder were pushed backward by the increasing growth, and, finally, in advanced cases one found at the internal urethral orifice a homogeneous tumor formed by the junction of these growths with the vesical muscle behind it. This was the common form of the so-called middle-lobe enlargement. The third form consisted in the growth and development of the prostatic glands, which were irregularly placed directly beneath the mucous membrane of the prostatic urethra, above the veru montanum. The enlargement of these glands, sometimes associated with enlargement of the middle isthmus, caused an intra-urethral growth, which pressed upward from the floor of the urethra, and by its progressive enlargement pushed back the muscular fibres of the bladder on the floor. In addition to these causes, which were the most important in producing the obstructions to the outflow of urine and vesical incompetence, there were two more, viz., (1) the overstretching of the vesical muscle, or atony; and (2) the structural changes in the walls of the bladder as the result either of prolonged inflammation, which was rare, or more commonly of chronic passive congestion resulting in the formation of the interstitial fibrous tissue in the bladder walls. Both of these weakened the muscular power of the bladder. From this it would appear that, theoretically at least, an operation deserving the name "radical operation for the relief of prostatic enlargement" must contemplate the removal of the mechanical obstruction, the relief of the venous stasis, the restoration approximately to its normal position of the attachment of the vesical muscle to the prostate, and the relief of congestion and inflammation of the bladder by drainage. Prostatectomy was the only operation which fulfilled all these conditions, and this operation, when done according to the method which he had heretofore described, would prove satisfactory in most cases. The theoretical objection to the Bottini galvano-cautery operation was that its object was solely to remove, and that only partially, the mechanical obstruction caused by the growth of the prostate. Of course, the burning through the obstructing portion of the prostate in this operation was likely also to relieve the œdema at first, but it was not claimed by its most ardent advocates that such a division of the prostate would restore, to an efficient state, the misplaced vesical muscle. The operation did not promise to accomplish efficient drainage of the bladder, yet this was absolutely necessary to cure the lesions resulting from chronic inflammation and from prolonged passive congestion. His own experience with the operation, although limited to a single case, had been most unsatisfactory; the patient had been relieved, after a few days, of his complete retention of urine, but he still required the use of the catheter several times a day, and the introduction of this was not made more easy by the operation. The immediate beneficial effects of the operation did not persist for more than four weeks, and the patient then, in spite of all efforts, relapsed into a condition of complete retention. He had seen several cases which had been operated upon by this method by well-known surgeons, and in all of these the ultimate results of the operation had been unsatisfactory. The best that could be said for Bottini's operation was, that it caused temporary amelioration in the symptoms of retention. He was inclined to think, from personal observation, that the good effects which were claimed for the operation were temporary, and certainly the patient who had been subjected to Bottini's operation was thereby rendered an unsuitable risk for any radical operation. He desired to protest against the views which were

being so freely expressed, by men whose opinion was entitled to respect, in favor of this operation; too much had been claimed for it. His own opinion was, that surgeons needed a better knowledge of what enlargement of the prostate meant—what anatomically and pathologically the disease really was. All cases were not alike—indeed, no two cases were alike. No one operation was certain to be suitable in all cases, nor to be equally satisfactory in all. It was a good thing to be progressive and to try new things, but it was most unfortunate to permit our enthusiasm to interfere with our scientific judgment.

**Technique of Perineal Prostatectomy.**—Speaking of the technique of the operation, Dr. Alexander said that unquestionably in most cases a suprapubic incision into the bladder was necessary in order to bring the prostate far down into the perineum. In two cases, however, he had been able to remove very large prostatic growths without resorting to the suprapubic incision. One of these cases was that of a very thin old man, and the other that of a patient with an exceedingly lax and flabby abdomen. In both cases it had been possible to pass the hand well down into the pelvic cavity without opening the abdominal wall, and to bring the prostate into the perineal incision. It was an open question whether the transverse or longitudinal incision into the perineum was the better. Up to the present time he had employed most frequently the longitudinal incision, and had found that the prostate could be removed through this with as much ease as when the transverse incision was made. It had the advantage of healing more rapidly, and of requiring less time to make than the transverse incision. The incision to be made into the prostate for the purpose of removing the growths was also still a matter of discussion. The method which he had usually adopted had been to divide thoroughly the floor of the membranous urethra up to, and perhaps a little into, the apex of the prostate; then, the prostate having been pushed as far down as possible into the perineum by the finger inserted through the suprapubic opening, he broke through the mucous membrane of the prostatic urethra as near the apex as possible, coming at once upon the enlarged lateral lobe, and being able to separate this without difficulty from the prostatic capsule. He was convinced that in his operation the floors and the sides of the prostatic urethra, anterior to the veru montanum, was torn through; the roof, however, of this portion of the canal was preserved. The prostatic urethra above the veru montanum was really an integral portion of the bladder, and it was this portion alone which it was necessary to preserve intact in order to obtain the best results. After having separated the lateral lobe from the capsule, the only difficult part of the operation was to separate it from the upper portion of the prostatic urethra without injury to the latter. This required a little time, but was not hard to accomplish. Having removed the tumors from the lateral lobe, he had never found it difficult to press down the existing so-called middle-lobe enlargement into the cavity thus formed, and enucleate it without injury to the mucous membrane of the bladder or prostatic urethra. If this method was employed, it was best to make the incision about a quarter of an inch below the apex of the prostate, and it should be deep enough to go through not only the prostatic capsule, but also well into the enlarged lateral lobes. The failures which had occurred in some cases had been due apparently to the fact that this incision had not been deep enough. This the speaker demonstrated clearly upon a specimen of enlarged prostate.

Dr. W. K. Otis said that he had had no personal experience with the Bottini operation, but was inclined to take the same view of it as did Dr. Alexander. Regarding the beautiful instrument presented he expressed the opinion that surgical procedures in the bladder could hardly go any further than catheterization of the ureter. Owing to the hemorrhage it did not seem to him that the advantages were commensurate with the trouble connected with this method of operation; and, moreover, the danger of hemorrhage and the greater liability to recurrence should lead the surgeon to select other and better known surgical methods. He would like to know what became of the tumors removed with these instruments; if there was not considerable likelihood that shreds of the tumors remaining behind would form nuclei of vesical calculi.

Dr. Meyer, closing the discussion, said that Nitze had especially stated that he operated only upon benign growth in the bladder. Many tumors that had been looked upon as malignant had proved ultimately to be benign. It was remarkable what large blood clots and large shreds of tumor would be discharged through these instruments. He was far from believing that every case of prostatic hypertrophy should be treated by the Bottini method; nevertheless, what he had observed from this method of treatment had deeply impressed him. The fact that Bottini had observed his cases for about twenty years should carry with it much weight. The least that could be said was that the method deserved, and should be accorded, a fair and thorough trial.

**Foreign Body in the Knee Joint Formed by a Piece of Cartilage Chipped from the Condyle.**—Dr. John F. Erdmann presented this specimen. It had been taken from the left knee-joint of a young girl. While turning, and running away from a playmate she had experienced sudden and severe pain, and this pain had recurred repeatedly until the time of operation, when it had been found that a small piece from the condyle had been chipped off. At the end of the third week she was moving about with perfect freedom.

### OUR LONDON LETTER.

(From our Special Correspondent.)

MEDICAL COUNCIL—LORD LISTER AT THE ROYAL SOCIETY—DEBATE ON RELATION OF TABES TO GENERAL PARALYSIS OF THE INSANE—ADJOURNED DISCUSSION ON OPEN-AIR TREATMENT.

London, December 8, 1899

After two days spent in its judicial work the Medical Council resumed its debates on Saturday, and continued until Tuesday. On that last day the programme was so crowded that not a little had to be left undone. The first subject taken up on Saturday was that of the title of licentiates of the Apothecaries' Society. Are they physicians or surgeons, or both? Of course this arises through the lamentable Hunter case. The society desired the council to join in a lawsuit to settle the question. Mr. Brudenell Carter, in proposing this course, read part of a very interesting letter from Dr. Murray, editor of the Oxford Dictionary, on the history of the word "physician." He said modern etymologists, looking at the classical derivation, are apt to think the words should have the original sense; but that would be to undo history, pull down the Tower of London, St. Paul's, and Westminster Abbey in order to restore Roman London. Interesting as the letter is in tracing the history of the word physician, it does not show the right of the licentiates of the society to adopt it, and the Council did not seem inclined to enter on a lawsuit, which might prove costly. For this we may congratulate ourselves so

far. The proposal was referred to a special committee to report to the Council.

There was another discussion on the proposal to obtain power to suspend a delinquent for a time from the advantage of being on the register, and restore him in due course, to give power to the licensing bodies in the same way to withdraw and restore their diplomas, and to give to the Council fines and penalties recovered under the medical acts. The draft clauses for such an act were approved, and the president is to ask the Privy Council to promote or support the bill.

Reciprocity of practice in reference to foreign countries was fully discussed in consequence of inquiries made by Germany and Italy. After long discussion of the matter on Monday and Tuesday, Mr. Horsley eventually carried a resolution requesting the education committee to consider the exemptions which are allowed to foreign graduates by various qualifying authorities.

The conduct of the two London colleges in admitting schools as places of preliminary scientific education, notwithstanding the view of the Council formally expressed, gave rise to some warm discussion. The colleges were evidently in the wrong, and it looked as if the Council would venture to insist on its authority, in as absolute a manner as the colleges repudiated it. But a body consisting of representatives of other oligarchies would not be too hard on those of the colleges, and so a milder course was adopted by a resolution adhering to the regulation of June 7th, and inviting these colleges to take the matter into fresh consideration. If they decline, the Council can no doubt refuse to register their diplomas in these cases. It was said this would fall on the students, but these would, of course, go to other qualifying bodies, if the Council had the courage to advertise its decision in the journals. Then the colleges would find their fees so diminished that they would soon be defeated.

Lord Lister's address at the annual meeting of the Royal Society was chiefly occupied with Mr. Haffkine's address on preventive inoculation, of which I gave you a report at the time. It is, therefore, unnecessary now to do more than say that Lord Lister indorsed Mr. Haffkine's process, and spoke in most favorable terms of Professor Wright's extension of the plan to typhoid; which is so satisfactory that many soldiers going to Africa are being inoculated. In the year's death roll of the society the noble president mentioned Sir W. Flower, Sir W. Jenner, Lord Herschell, Sir W. Roberts, Sir Edward Frankland, Dr. Henry Hicks, and Professor Bunsen.

The discussion at the Pathological Society on "The Relation of Tabes to General Paralysis of the Insane" has been adjourned, so we have now on hand two important adjourned debates at two leading societies. The debate was opened by Dr. F. W. Mott, who illustrated his communication by lantern slides and microscopical preparations. He considers the pathological process in the two diseases as identical—viz., a primary progressive degeneration of the neuron with secondary sclerosis and inflammatory or sub-inflammatory conditions in the vessels or adjacent membranes due to irritation, caused by the products of degeneration and a formative degeneration of the glia elements. In tabes the changes in the posterior columns closely resemble those produced by cutting the roots. Dr. Mott has found in conjunction with Professor Sherrington that loss of muscular tonus is a most marked effect of section of posterior roots. He has found no chromolytic changes, however, in the cells of the posterior ganglia after section in monkeys. In six cases of tabes he found excess of pigmentation with some shrinking and irregularity. In two there were definite chromolytic changes, but in both of these the peripheral nerves were affected. As to the appearances in the cord in the tabetic form of general paralysis, there are differences of opinion. In Dr. Mott's specimens the lesions are those of tabes, and in the brain there are changes more or less typical of general paralysis. If these are borderland cases he would consider them a link in the chain of evidence that the two diseases are results of the same morbid process, differing only as it affects different parts. Dr. Mott holds that the most important factor of both diseases is syphilis. If the evidence hardly amounts to a proof that with no syphilis there could be neither tabes nor general paralysis, he thinks we might almost infer as much, and regard the two disease as parasyphilitic. He has seen twenty-two cases of juvenile general paralysis, and in eighty per cent. there were signs of a history of syphilis, and in the others this could not be excluded. A similar relationship to juvenile tabes has been remarked in recorded cases, and various clinical phenomena point in the same direction.

Dr. Alexander Bruce, of Edinburgh, said the posterior roots entered the cord quite differently from the anterior, for they were sharply constricted, and the medullary sheath became much thinner. Further around the point of entry was a blood-vessel, and in early cases he has seen a distinct thickening here such as syphilis might produce. This may perhaps explain the limitation of the disease to the parts within the cord. Dr. Bruce questioned whether the nerve changes were primary, for he had seen hyaline degeneration of vessels before any marked nerve changes could be detected. He had also frequently found inflammatory foci with dilated vessels and round cells scattered through the cortex. As to the action of toxins, that might just as likely affect vessels as nerves.

Dr. Buzzard did not profess himself qualified to discuss the pathological changes, but testified to the extreme importance of Dr. Mott's paper and demonstration. Clinical observation was largely concerned, and he agreed that the most important factor was syphilis. Dr. Mott's unique experience in juvenile general paralysis appeared to be overwhelming evidence of this. He was also disposed to admit the unity of general paralysis and tabes. He thought both diseases could in many cases be regarded as primary degeneration of the neuron, with secondary inflammatory or subinflammatory changes in the meninges and proliferation of the glia cells, but not always so. The two processes might sometimes go on side by side, as he felt sure was the case in insular sclerosis. He thought it premature to exclude the soft sore as a possible source of a toxin distinct from syphilis, but capable of setting up the degenerations in question, just as in multiple peripheral neuritis, whatever the toxin that set it up, the changes were the same.

On resuming the debate at the Medico-Chirurgical Society, Sir D. Powell said he thought the name "open-air treatment" unfortunate as ignoring other factors, while sanatorial was as bad as indicating the necessity of a special building. Any "catch-name" was undesirable. Sanatoria were useful for many who had no home in which they could be properly treated, and also for the medical men who had the care of them. The whole consumptive population could not go to sanatoria. The object was to check the spread of the disease, remove the patient from the conditions in which he was attached, and starve out the microbes. The evidence of progress was the temperature, the chief point being the excursions of the curve. He did not advocate the rectal method. Among other objects to promote repair was good cooking. The physicians should superintend the distribution of the food. It was a doubtful advantage to increase the weight above the patient's normal, as it might be

gained beyond the capacity of the lungs and heart, and so add to the breathlessness. In the apyretic periods graduated exercise, such as walking ten minutes and resting fifty in the hour as indicated, care as to work and climate, after leaving a sanatorium, was necessary, *e.g.*, return to city life might mean collapse.

Sir H. Weber regarded sanatoria as essential for the poor, and useful for others. He did not agree with Dr. Fowler that the system was the principal factor. The medical man was as important, if not more so, for the system could not allow for the constitution of the patient. In febrile states exercise should be avoided. He had known patients to perish on climbing a hill, and a heated discussion to prove the beginning of the end. This made him insist on the importance of medical supervision, and the doctor must regulate the treatment in each individual. Too much air, even too much light, might injure some individuals. Mental excitement was another point. He had noted a rise of one, two, three, and even four degrees in hospital patients on visiting-days.

Dr. A. Ransome recalled that Sir J. Clarke, Dr. H. MacCormac and others had employed fresh-air treatment, but Brehmer systematized the plan which yielded the best results. He did not advocate a hard and fast routine. The method was really treatment by pure air—a sort of aseptic medicine. How it acted might be explained more or less by various hypotheses. Happily a sanatorium was not indispensable, for many patients must be treated in their homes.

Dr. Heron was sure the method could be carried out in the patient's home if he was intelligent. The most hopeful cases were, of course, in the early stage —say a slight infection of one or even both lungs with a temperature not above 99.5° F. If above 100° F. the case was probably a mixed infection. Some rules in sanatoria were needless and irritating. A daily visit of the doctor and frequent temperature taking were irksome and unnecessary. Active exercise was often useful, and many poor patients could work at out-door employments, farming, gardening, etc. Sanatoria should not be commercial speculations.

Dr. Squire said the more complete was the open-air treatment the better were the results, but after twelve years' experience of fresh air as distinguished from sanatoria he admitted some patients could not bear it in all climates. He mentioned some contraindications. Diminution of temperature in cases with a wide daily range should be watched lest collapse supervene. Bronchitis cases would not bear much exposure to cold air. Hæmoptysis was not a contraindication. Many relapses occur after the patient has returned to work for a year. Over-feeding is not always beneficial.

Dr. Poore said an arctic climate might prevent lung disease, but would not make existent bronchitis better or worse. He dwelt on the construction of sanatoria.

Dr. Hillier referred to the discussion held years ago, introduced by Dr. MacCormac, which was not favorably received. Open-air meant pure-air treatment, absence of respiratory impurities. These are effete animal products—toxic to the host but nutritious to the bacilli. These vegetable organisms flourished on the effete animal products—a form of manure.

**Hemorrhoids.**—Eighteen failures led me to the belief that dilatation is of no value whatever, even in small piles, no matter whether internal or external. I would recommend in such cases that the local treatment with good but non-toxic antiseptics be given a fair trial. It is hardly necessary for me to mention that attention must also be paid to the possible removal of mechanical disturbing influences.—Gustavus M. Blech.

## THE TREATMENT OF APPENDICITIS.

To the Editor of the Medical Record.

Sir: On page 878, Medical Record, December 9th, Dr. Morris says: "As far as I am aware, no physician has as yet been able to defend medical treatment of any sort when proper treatment is available." This statement is obviously unfair. I might say with equal if not more accuracy, that "no surgeon has as yet been able to defend the exclusively surgical treatment of appendicitis when proper treatment is available." I am sure he will never find any one, physician or surgeon, who wishes to defend any treatment, medical, surgical, or any other, when proper treatment is available.

Dr. Morris' remarks on "proper" treatment reminds me of Andrew Jackson and the tariff. A committee was sent to him to find out whether he favored a protective tariff or a tariff for revenue only. "Gentlemen," replied the general, "I favor a judicious tariff." Now, I have the highest opinion of Dr. Morris as a surgeon; so have many physicians all through the country. However, physicians are not yet willing to concede to Dr. Morris that the exclusively surgical treatment is the only treatment in appendicitis. The exclusively surgical treatment and the treatment which, by careful selection, has come to be the regular routine with most of our physicians, do not show such a marked difference after all. The general practitioner favors operation in all his recurring cases; so does the surgeon. His acute cases the physician treats medically as a rule. In a very small percentage of his primary cases he may find pus developing, or after a few days prolonged high pulse, or perhaps severe continual pain with extreme rigidity of the muscles in the right iliac fossa, or other symptoms upon the development of which he, from experience and observation and what he has culled from the experience of others, may, and probably will, advise the calling of a surgeon with a view to operation. We believe that appendicitis cases managed as above receive the very best treatment that is available to-day, and one that will save more lives than the exclusively surgical plan. As to which plan is the better, reliable data can alone determine. Now, what constitutes reliable data? I believe that physicians can draw more practical conclusions from the means at their command than the hospital surgeon with all his statistics. The general practitioners mingle with physicians of their own county or vicinity, and have the benefit of one another's experience, impressions, and observations. Then some of their number attend meetings where physicians from a whole State or country are represented. The physicians return home, relate the results of their mission, the various treatments and results therefrom are dissected, and finally the consensus of opinion is thrown to some particular method differing a little in detail perhaps, but tending on the whole to reduce the mortality of the disease to its lowest possible percentage. Untrustworthy, Dr. Morris may say, but nevertheless they are worth more to the general practitioner than all the hospital statistics he has at his command. The statistics of a hospital may be all right for hospital practitioners, but are practically worthless for general practitioners. For instance, what interest have the discussions of the boasted methods of treatment of typhoid fever in the hospitals when they show a mortality of from seven to twenty per cent., while we have a death rate of from one to five per cent.? Or, again, in pneumonia the hospital statistics show a mortality rate of from twenty to forty per cent.; while it is a matter of common knowledge that the general practitioner in his private practice has a rate of only three to six per cent. I might quote other diseases with like comparisons. Hospital statistics may be all right

for hospital treatments, but for outsiders they are practically of no use.

On page 877 Dr. Morris quotes Dr. Rupp as saying, "Cases differ, and consequently they demand different methods or plans of treatment," and makes this reply: "My argument is that appendicitis cases are due to bacterial infection and are consequently alike." Nothing could be farther from the facts than that statement. It does not follow at all that appendicitis cases are alike because they are caused by bacterial infection except it be in their etiology. Typhoid fever is caused by germ infection, but every case is a law unto itself as to details of treatment. Given ten cases of typhoid, and the probabilities are that each case will differ from the other in many of its phases, and no two of them will be treated alike. Some patients have diarrhœa, others are constipated throughout the course of the disease; some have severe gastric symptoms, others none at all, and still all are caused by the same germ infection. And so with hosts of other diseases, appendicitis not excepted. Again, he says that "fifty thousand people die in the United States each year from appendicitis." Allowing that there were fifty million persons of suitable age for contracting the disease, that would be one death to every one thousand of population.

If each one of those who were susceptible should, after reading of the treatment of appendicitis from a surgical standpoint, say to himself: "I am just as liable to have appendicitis as anybody else; there is a great surgeon in the adjoining city who will remove my appendix, and I won't be half so liable to die from the operation as I would if I had the measles," and granting the surgeon the extreme low mortality of one per cent., there would be five hundred thousand deaths from the operation alone. That the physicians are none too conservative in refusing to advise operation in every primary case that comes along, however slight, will, in my opinion, be conceded in the near future by physician and surgeon alike. The physician is always open to conviction, and if Dr. Morris can convince the general practitioners that his way is the right way and will save more lives than ours, we are prepared to follow, but not merely on his say-so.

He asks us to tell him as to our cases, "length of time wasted in bed, state of health after subsidence of acute attack, and of the state of the appendix by accurate palpation."

Let him also tell us of hernia pads worn for months of operations that did not relieve pain, and subsequent operations for adhesions; of operating for diseased appendix, and removing an inflamed ovary which was the cause of the trouble; of operating only to push a displaced kidney back into position; of those who succumbed to anæsthetics; of those whose kidneys or other internal organs have been damaged by the ether or chloroform, and of other little things that we physicians consider before we send a perfectly healthy man who has had appendicitis once, and probably never will have it again, to him to be operated on. As to palpation, I believe that its indiscriminate use as a means of diagnosis is susceptible of much harm in hands less skilful than perhaps Morris or Edebohls, especially in those cases in which there is a probability of abscess. That pressure is liable to rupture the thin wall that nature has thrown up to keep pus out of the rest of the abdominal cavity was shown in this vicinity a short time ago. An operation was advised, a specialist was sent for, an incision was made down to the peritoneum, and just as the surgeon was going to incise the peritoneum he felt something give way beneath the slight pressure of his fingers. He continued the operation to find that the slight pressure had broken the wall thrown up to confine the pus, and it had flooded the abdominal cavity. In spite of every endeavor general fatal peritonitis followed. That palpation is a great help in differentiating suspected cases I know from recent experience. That the exclusively surgical treatment of primary appendicitis will ever supersede the "mixed" treatment of the physicians is practically out of the question; and the surgeon who thinks it will is liable to be grievously disappointed. The "mixed" treatment is here to stay until the general practitioners find something better, but that something is not located in the exclusively surgical method. However, we will all, physician and surgeon alike, agree heartily with Dr. Morris that all other methods or plans of treatment should be discarded when the "proper" treatment is available.

J. S. Horner, M.D.

West Pawlet, Vt.

## ORIGIN OF THE TERM APPENDICITIS.

To the Editor of the Medical Record.

Sir: In the communication of Dr. A. Rose to the Medical Record of December 9th, he inquired who first suggested the name "appendicitis," and as I could not answer the question myself some years ago, I inquired of Dr. J. B. Murphy, of Chicago, if he could tell me, and he sent the following answer:

"In reply to yours of December 3d, I will say that, as far as I have been able to find out, the first time that the term was employed was in a lecture in 1871, by Henry Draper, then professor of physiology in the medical department of the University of New York. He apologized for using a hybrid term, whose origin he was unable to state, which had been applied to the inflammation of the appendix vermiformis produced by foreign bodies. The lecture dealt with the affections of the intestinal canal. The term in all probability has long been current in English-speaking countries, and may date back to the time when there was less objection to yoke a Greek and Latin word together than there is at present. It was somewhat difficult for me to get this information, but with the assistance of my friend, Dr. James J. Kiernan, it was located in this country."

This is the nearest to the origin of the word "appendicitis" I ever heard, and I therefore send this communication to you, thinking that the readers of the Medical Record might be interested in it.

J. H. Carstens, M.D.

Detroit, Mich.

## THE NOMENCLATURE OF APPENDICITIS.

To the Editor of the Medical Record.

Sir: In your issue of December 9, 1899, Dr. A. Rose, commenting upon my paper, "A Review of the History and Literature of Appendicitis," which appeared in the Medical Record of November 25, 1899, criticises what I have written on the nomenclature of appendicitis, and formulates a demand for the name of "the benefactor of mankind" who has given us the word appendicitis.

The crisicisms of Dr. Rose are in part just. The one sentence, "Epityphlitis, ecphyaditis, and scolecoiditis have been proposed by Kuester, Morris, and Gerster, respectively, as synonyms for appendicitis," contains, I hope and believe, all there is of carelessness and inexactitude in my entire paper. A more accurate statement would have been: "Kuester first proposed epityphlitis as a synonym for appendicitis. Morris and Gerster were the first ones I personally heard use the terms ecphyaditis and scolecoiditis respectively."

In regard to the omission of perityphlitis as a synonym for appendicitis, with which I am charged

by Dr. Rose, I hold that these words are no more synonymous than are, for instance, perimetritis and salpingitis.

Dr. Reginald H. Fitz, of Boston (*American Journal of the Medical Sciences*, 1886, n. s., xcii., page 323), as far as my knowledge goes, coined and first used the word appendicitis. G. M. EDEBOHLS, M.D.

December 25, 1899.

## Medical Items.

**Heredity and Alcoholism.**—A physician who is a professor in a medical college has recently published an elaborate argument to prove that inebriety cannot be transmitted because it is a nutritional disorder. An eminent divine discovers from the theological point of view that inebriety cannot be transmitted, and disposes of the subject in a bitter condemnation of the foolishness of students who are trying to know something of the subject from the physical side. A man of letters has joined the objectors to heredity, and with some feeling condemns all efforts to sustain what he calls a great delusion. A self-assertive editor has delivered himself in oracular sentences at some length along this line, and discovers much danger in the heredity theory. Thus the tide of criticism goes on building up and strengthening the facts by denying their accuracy. In this way attention is turned to them and new inquiry and new examination follow, and the facts become firmer, clearer, and better known. Denials and contradictions of facts are never destructive, but always constructive if the facts are vital and real.—*Journal of Inebriety.*

**Menopause.**—There is no positive sign of the menopause. The menopause does not necessarily coincide with the cessation of ovulation, and there is no certain sign of inability to conceive.—CERF.

**Compositions of German "Infant's" Milks.**—Drs. Schwabb and K. B. Lehmann have determined the compositions of a number of so-called "infant's milks" in the German markets, with the view of ascertaining how far they fulfilled their claims to resemble breast milk. Of the twenty varieties of infant's milks examined the great majority contained an excess of casein and were deficient in sugar—that is to say, were too little removed in character from crude cow's milk; and a large number had so low a percentage of fat as to suggest their having been partially skimmed, or at least diluted with a view to a reduction of the casein. The closest approximation to human milk was presented by the specialties of the Würzburger Dampf-Melkerei with casein and albumin 1.11, fat 3.4 to 3.65, and sugar 5.98 to 6.10; and the advertised composition of the "Nutricia" of Hanover, with casein and albumin 1.7, fat 3.35, and sugar 6.2, though the actual percentages found were 1.28, 3.0, and 4.76 respectively. Gaertner's "Fettmilch" contained casein and albumin 1.4 to 1.7, fat 3.1, and sugar 1.88 to 1.99. —*Public Health.*

**Pneumatic Cure for Baldness.**—*The Canada Lancet* says: "There has recently been advertised a pneumatic cure for baldness. This is based on the old, old theory that the loss of the hair is caused by a diminished blood-supply with resulting atrophy of the hair bulbs. Positively the last thing in the treatment of this affection is what is known as a 'capillary chalice.' We trust that our denominational friends will not be shocked at this use of the word, but will take the broader view that is derived from the Latin *calix*, meaning a cup, and that it is only within the last half-dozen centuries that the word has been specifically used to designate the communion cup. Besides, to what more noble purpose could an instrument with any name be applied than in the relief of baldness, the deformity of youth, and scarcely to be borne with equanimity in old age? The mechanism of this treatment is simply the old one of cupping. The chalice is nothing but a hollow rubber pad from which the air can be exhausted, and in this way the circulation of the scalp stimulated so as to produce healthy hair follicles and stimulate the normal growth of the hair. We are left in no doubt as to the efficacy of the treatment, for the advertisement of the company selling the instrument contains a number of illustrations of 'before' and 'after' treatment. A number of men are shown with remarkably smooth pates, and later we see the same heads covered with hair that would be the envy of any barber in the land. We are informed that the 'chalice' does not aim to produce a perfect vacuum, which of course nature abhors, but that it is only a partial one. We are gratified at this conservatism on the part of the makers of the cup, because a perfect vacuum might result in a loss of a portion of the scalp and there would be little hope of restoration, as even with this method of stimulating the circulation it could hardly be hoped that the denuded cranium could produce a luxuriant crop of hair."

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended December 23, 1899:

| | | Cases. | Deaths. |

Campbell, James, death of, 597.
Canadian Medical Association, 423.
Cancer, diagnostic and prognostic value of adenopathies in epithelial, 824; giant cells in, 926; heredity in, 807; incidence of, 986; increase of, in New Zealand, 178; infectivity of, 762; meat eating as a cause of, 72; multiple primary, 88; of the breast, oöphorectomy in, 804; of the breast, rational surgical treatment of, 498; of the breast, treatment of, 390; of the jaw, operation for, 348; of the liver, successful resection of, 522; of the penis, total emasculation for, 392; of the rectum, abdomino-sacral method of removal of, 217; of the stomach, early diagnosis of, 577; of the uterus, 243; of the uterus, early diagnosis of, 422, 874; of the uterus, total abdominal hysterectomy for, 312, 498; of the uterus, treatment of, 389; of the uterus, vaginal hysterectomy for, 926; parasite of, 88; pathogenesis of, 460; secondary infiltration of, treated with guaiaquin, 134; serum treatment of, 21; statistics of, 501; traumatic theory of, 91, 344; treatment of, 427; treatment of, by its own toxins, 870; vegetable, 166; water supply in relation to, 22.
Carbolic acid, poisoning by, 241.
Carcinoma gelatinosum (mucosum), 753.
Card, David C., death of, 597.
Carlisle, Stuart B., death of, 902.
Carstens, J. H., origin of the term appendicitis, 986.
Carter, G. Herbert, intestinal obstruction in a new-born child, 133.
Casts, renal, significance and detection of, 586.
Cataract, abortion of immature, by combined manipulation and instillation, 591; congenital, removed by operation, 735.
Catarrh, treatment of nasal, 212.
Catheters, 644.
Centenarians, 382, 916.
Central Park, manuring of, 560, 726.
Century, medical progress during the, 169, 277.
Cerebellum, successful treatment of tumor of the, by trephining and drainage, 927; tuberculoma of the, 196.
Cerebrospinal meningitis, 739; in the Soudan, 808; Kernig's sign in, 232; lumbar puncture in, 681; spinal-cord changes in, 706.
Cervix, anaplastic amputation of the, in regard to subsequent pregnancy, 496.
Chalfont epileptic colony, 144.
Chandler, Charles F., honor for, 166.
Chapman, Henry C., notice of book by, 96.
Chapin, Henry Dwight, the question of gruels in the feeding of infants, 181.
Charcot as an artist, 467.
Charing Cross Hospital, bazaar in aid of the, 106.
Charitable institutions, incorporation of, by the State Board of Charities, 655.
Charity, abuse of medical, 174; public funds for private, 414, 416, 596.
Charpentier, Louis Alphonse, death of, 201.
Chest, comparative measurements of the, 159, 805; diseases of the, 173.
Cheyne, W. Watson, notice of book by, 383.
Chicago Medical Society, 19.
Chipp, Dr., death of, 634.
Chloral habit, cure of the, 162.
Chloroform, anæsthesia with, 682; disguising the odor of, 606.
Chlorosis, thombosis in, 860; treatment of, 831.
Cholangiostomy, two successful cases of, 683.
Cholecystectomy, indications for, 681.
Cholecystitis, pain in, 394.
Cholelithiasis, medical and surgical treatment of, 979.

Cholera, preventive inoculations against, 143, 176; treatment of, 751.
Chorea, Huntington's, 557; infectiousness of, and relation to rheumatism, 744; oil of gaultheria for, 207; treatment of, 242.
Christian, R. B., report of a case of cerebral meningitis manifesting extraordinarily high temperature, 337.
Christian science, 18, 128, 236, 538, 559, 610, 689, 763.
Church, Archibald, notice of book by, 96.
Circumcision, evils of the ritual practice of, 302, 394; necessity and advantages of, 174.
Class, W. J., supplementary note on the etiology of scarlatina, 513; the etiology of scarlet fever, 330.
Clay dressings, 359.
Cleaveland, Trumbull W., failure of a suit against, 21.
Clendenen, Floyd, the treatment of typhoid fever, 572.
Clendenin, Paul, death of, 58.
Clinical Society of Maryland, 596.
Clothing and etiquette, 288; poisoning by means of, 807; winter, 951.
Club-foot, treatment of, 495.
Coakley, Cornelius Godfrey, notice of book by, 970.
Coblentz, Joseph, death of, 274.
Coblentz, Virgil, notice of book by, 96.
Cocaine habit, cure of the, 162.
Coccidial infection, a case of, 65.
Coccygodynia, treatment of, 60.
Cochran, John H., death of, 597.
Cockles, typhoid fever spread by, 465.
Cod-liver oil, to disguise the taste of, 211.
Coe, Henry C., notes on the induction of premature labor, 46.
Cœliotomy for uterine disease, 388; hernia following, 979; management of post-operative hemorrhage of, 531; the operation of, 226.
Coffee, 71.
Coghill, Sinclair, death of, 34.
Colchicum, wholesale poisoning by, 166.
Cold, therapeutic applications of, 16.
Coleman, Warren, the relations of cardiac murmurs to the events of the normal cardiac cycle, 87.
Coley, W. B., congenital hernia of the umbilical cord, 667.
Coli bacterium, infection by the, 244.
Colic, treatment of, 60, 419.
College of Physicians of Philadelphia, 561, 745, 902; Section on General Medicine, 748.
Colles' fracture, approximation by short lateral splints after, 159; treatment of, 797.
Colon, treatment of the abdominal viscera through the, 600.
Colorado State Medical Society, 200.
Colpohysterotomy in the treatment of inversion, 423.
Colporrhaphy, 388.
Coma, diabetic, saline infusion in, 483.
Commercialism in medicine, growth of, 793.
Commissions to physicians, 487, 500, 524.
Congresses in Paris in 1900, 678.
Congress, international medical, at Paris, 380, 631, 866, international, of gynæcology and obstetrics, 312, 420, 457, 495; of Italian Alienists, 561; on medical ethics, 56; Pan-American, 745.
Conjunctivitis, treatment of acute, 243.
Connecticut State Medical Society, 20.
Constipation, 66; causes of, 771; in infants, 24; in infants, treatment of, 455; operative treatment of, 570; treatment of chronic, in children, 211; varieties of, 557.
Consultation, ethics of, 307.
Consumption, increase of, in prisons, 216.
Consumptives, action against, in Colorado, 631; Baltimore Hospital for, 679; management of poor, 425; Muskoka cottage sanatorium for, 424; proposed quarantine against, in California, 449, 453; recommendations of the New York State Board of Health regarding, 55; release of, from prison, 57; sanatorium for, in Illinois, 345; sanatorium for, in Italy, 632; sanatorium treatment of, at home, 638; State care of, 68, 613, 638, 647, 724. See also *Tuberculosis*.
Contagious diseases, notification of, 359; prevention of, 921; weekly statement, 36, 71, 107, 179, 251, 288, 324, 395, 430, 466, 502, 538, 574, 656, 691, 726, 767, 807, 843, 878, 916, 950.
Continental Anglo-American Medical Society, 345.
Convulsions in infancy, 26, 592; leucocytosis associated with, 196.
Cook, Frederick A., return of, from an Antarctic expedition, 21.
Cookery, instruction in, for medical men, 574.
Coombs, G. H., volvulus of the cæcum, 685.
Coroner, criticism of a, 378.

Hæmostasis by gelatin, 974; in intrapelvic surgery, 114.
Hæmostatic, gelatin as a, 179, 974.
Hair, sudden change of color of the, 612.
Hall, Harry O., the etiology of scarlet fever, 697.
Hamburg, D. J., treatment of pulmonary œdema of cardio-neurotic origin, 241.
Hamilton, John V., death of, 201.
Hancock, James Cole, headaches due to eye strain, 668.
Hand as an obstetrical instrument, 715; asepsis of the, 88, 101, 672; deadness of the, 804.
Hansell, Howard F., notice of book by, 311.
Hardenbergh, Daniel B., hypertrophies in the tonsillar ring, 787.
Hare, Hobart Amory, notice of book edited by, 23, 95.
Harlem Medical Association, 93.
Harris, Dr., death of, 346.
Harris, E. Eliot, notice of medical directory edited by, 798; testimonial to, 677.
Harrison, Reginald, notice of book by, 240.
Hartmann, Dr., notice of book by, 131.
Hartmann, William D., death of, 310.
Harveian oration before the Royal College of Physicians, 723.
Harvey, Thomas W., relapse in measles, 838.
Hassenplug, J. H., death of, 867.
Hats, character shown in, 878.
Hawaiian Islands, climate of the, 431.
Hawkins, Rush C., the unfavorable winter conditions of Egypt, 654.
Hay fever, treatment of, 419.
Head, intracranial drainage, 391.
Headache, eye affections in relation to, 628, 668, 972; hot air in the treatment of, 557; of nasal origin, 106; powders, dangers of, 477; treatment of, 821, 903.
Healing by first intention, some conditions of, 101.
Health and doctors, 396; inequality in the inheritance of, 70; reports of the Marine-Hospital service, 36, 72, 108, 144, 180, 216, 252, 288, 324, 360, 396, 432, 468, 504, 540, 576, 612, 692, 728, 772, 808, 844, 880, 916, 952, 987.
Hearing, effect of atmospheric changes on the, 738.
Heart, action of the diphtheria poison on the, 340, 893; arrhythmia of the, 703; carbonic-acid gas in disease of the, 385; digitalis in disease of the, 61; effect of gout upon the, 790; electricity in failure of the, 695; failure of the, 831; gumma of the, 671; gunshot wound of the, 894; mercury in diseases of the, 972; murmurs of the, 804; new explanation of the presystolic bruit, 467; relation of murmurs of the, to the events of the normal cardiac cycle, 87; treatment of wounds of the, 304.
Heat fever, 321; therapeutic employment of, 494.
Heffenger, A. C., hæmostasis in intrapelvic surgery, 114.
Heiman, Henry, a case of crescent malaria occurring in a boy aged five years, always resident in New York, 241.
Helferich, H., notice of book by, 23.
Hemihypertonia, post-apoplectic, 972.
Hemmeter, John C., the early diagnosis of cancer of the stomach, 577.
Hemorrhage, causes of secondary, 761; in the new-born, treatment of, 574; treatment of post-partum, 822.
Hemorrhoids, complications met with before and after operations for, 566; liniment for, 751; modern surgical treatment of, 567; modification of Whitehead's operation for, 66; post-operative treatment of, 66; treatment of 212, 499; treatment of internal, 823.
Hendricks, George A., death of, 490.
Heredity of alcoholism, 987.
Hermaphroditism, a case of so-called, 221.
Hernia, Bassini's operation for, 622; causes of, 390; dressing for umbilical, 722; following operations for appendicitis, 102; inguinal, 64; inguinal, in the young, 931; new operation for inguinal, 555; of the umbilical cord, 667; of the vermiform appendix, 303; operative treatment of, 231; radical treatment of, 682; retained, 641; treatment of strangulated, 761.
Heroin, poisoning by, 831.
Herrick, Clinton B., notice of book by, 132.
Hezel, Otto, notice of book by, 96.
Hiccough, obstinate, during the puerperium, 715.
Hicks, Francis Edward, death of, 465.
Hicks, John Wale, death of, 724.
Higgins, F. W., anomalous pupillary reaction, 948.
Hill, Charles Howard, death of, 167.
Hill, L. L., hernia of the vermiform appendix, 303.
Hip, congenital dislocation of the, 493; dislocation of the, in tabes, 521; excision of the, with skiagraph taken after five years, 517.
Hip-disease, management of the deformity of, 469; treatment of, 494.
Hirt, Ludwig, notice of book by, 491.
Hitchcock, E., comparative chest measurements, 805.
Hoffman, Walter J., death of, 749.
Hollopeter, W. C., notice of book by, 239.
Holzhausen, Charles H., death of, 714; fracture of the arm in a new-born child, 715.
Hopkins, Herbert J., foreign bodies in the throat, 13.
Horner, J. S., the treatment of appendicitis, 985.
Horner, Robert, death of, 167.
Horseflesh as a food, 539.
Horse sickness in South Africa, 862.
Hospital abuse, newspaper discussion of, in London, 464; an ancient Roman, 950; corps of the United States army, 57; robbery of a, 680, 711; ship *Relief*, unseaworthiness of the, 454; ships, British, 712; liabilities for the treatment of pay patients in, 233, 934; operations in European, 81.
Huber, John B., a real charity—a tribute to the late Dr. Crampton, 429.
Hueppe, Ferdinand, notice of book by, 131.
Hughes, Daniel E., notice of book by, 798.
Humphreys, D. S., removal of a foreign body from the nose, 835.
Hunterian oration in 1823, 324.
Hunter, Robert, death of, 201.
Hupp, Frank Le Moyne, the present status of appendicitis, with report of forty-five cases, 436.
Hydatid mole, 242; of the liver, suppuration of, with rupture into a bronchial tube, 975.
Hyde, R. E., triplets, 771.
Hydrocele, resection of the tunica vaginalis for, 682.
Hydrocephalus with pseudo-spastic spinal paralysis, 552.
Hydropericardium, treatment of, 211.
Hydrophobia, see *Rabies*.
Hydrorrhœa gravidarum and hydrosalpinx, 637.
Hygiene, domestic, in America and Great Britain, 235.
Hymanson, A., a case of acromegaly, 14.
Hypnotics, Croonian lectures on, 250.
Hysterectomy, abdominal, in connection with Cæsarean section, 422; new procedure in abdominal, 461; technique of abdominal, 536.
